METALLURGICAL AND CHEMICAL ENGINEERING

A Monthly Journal being the Incorporation of
Electrochemical and Metallurgical Industry
and Iron and Steel Magazine.

VOLUME VIII

From January to December 1910

436833
3. 7. 45

NEW YORK
ELECTROCHEMICAL PUBLISHING CO

INDEX TO VOLUME VIII

GENERAL ALPHABETICAL INDEX

*Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest). Illustrated articles are indicated by.**

A

ABBOTT, H. B 605
Abbott Ball Co..... 600
Abel, J. J..... 638
Abrasives, Alumina. Saunders and Jeppson, (P.)..... 290
Acetate of lime. Klar..... 434
——Campbell 155
Acetic acid 158, 434
Acetone 150, 434
Acetylene tetrachloride. (S.)..... 96
Acheson, E. G. 4, 59, 63, 293
——Presentation of Perkin medal..... *69
Acid egg. Automatic. Meade..... *545
——Schutze *373
Agassiz, R. L..... 304
Ageing liquors. Seitz (P.)..... 433
Agriculture and metallurgy..... 313
——(See also Smelter fumes.)
Air-moistening apparatus..... *704
Albergeer Condenser Co..... *551
Alkali bromide electrolysis. Foerster and Yamasaki (S.) 427
Allegheny Plate Glass Co..... 358
Allis-Chalmers Co., 56, 57, 384, 483, 553
Alloys.
——Aluminium-calcium. Breckenridge . 349
——Antimony-lead, Shrinkage. Ewen and Turner (S.) 641
——Antifriction. Stratton. (P.)..... 693
——Iron in ferro-alloys. Girod..... 530
——Manganese-aluminium. Haynes 652
——Copper (P.)..... 367
——Copper-aluminium-manganese 154, 202
——Copper-arsenic. Bingham and Hill. (S.) 95, 141
——Copper-chromium. Nasilty and Scanlin (P.) 690
——Defects (Review) Hiorns (S.) 642
——Electrolytically deposited. Field. (S.) 206
——Failure of high engineering alloys. Low 495
——Iron-copper *68, *70, 72
——Iron-nickel-aluminium *131
——Magnesium-Pistor and Rakowica. (P.) 690
——Magnetic, from non-magnetic materials 562, 640
——Near Arsenic. Friedrich..... 190
——Nickel-manganese for resistance. Dewey (P.) 99
——Phosphor-bronze 98, 145
——Pyrophoric. Dewey (P.) 595
——resistance wire. Dewey (P.) 412
——steels. (See Iron and Steel.)
——Zinc-iron. Seward and Kilgelgen (P.) 99
Aluminium Research Committee, British Electrical Metallurgical Engineering 145
Aluminium, crucibles and refractories for. Saunders and Jeppson (P.) 99
Aluminium-manganese alloys. Tone (P.) 412
Electrolytic Tone Danckwardt (P.) 604
Furnace for. Schwahn (P.) 147, 692
Furnace for laboratory. Neumann and Dietz *186
Aluminium furnaces. Dewey (P.) 1
Aluminium-nickel alloys. Breckenridge 140
Aluminium-silicon alloys. Mixter and Wolff. (S.) 94
Aluminium, Production 310
Aluminium, Production in Denver. Pastor 12
Aluminium-silicon-nickel alloys. Treatment. Cito *141
Arsenic-copper alloys. Bengough and Hill. (S.) 95, 141
Arsenic, Native arsenical silver ores. Dewey (P.) 161
Assay of gold alloys. Smith (S.) 92, 145
Assay values. Standardization 411
Astatine. Tames 47
Atlas Power Co..... 196
Atmosphere, Oxygen section. See Nitric Acid from air, also Carbide from air, also Ammonia synthesis.)
Atomic weight of valence. Hostetter 200
Averaging instrument for circular short records *440
American Association of Commerce and Trade 652
American Blower Co..... 437
American Chemical Society..4, 64, 113, 274, 310, 372, 387
——San Francisco meeting..... 538
——Train wreck *446
——Western tour 517
American Cyanamid Co..... 227
American Electrochemical Society..... 113
165, 171, 174, 224, 274, 446, 517, 558
——Chicago meeting *627
——Pittsburgh meeting *329
American Ferrofix Brazing Co..... 166
American Foundrymen's Association, 174, 310, 603
——Detroit convention 436
American ingot iron..... 61, 98, 225
——Aupperle *262
American Institute of Chemical Engineers, 4, 174, 310, 658
——Niagara Falls meeting..... 386
American Institute of Electrical Engineers 176, 394
American Institute of Mining Engineers. 74
——Canal Zone meeting..... 700
American Iron and Steel Institute..... 441
——New York meeting..... 626
American Lava Co..... 166
American Metal Market Co. 214
American Oxhydric Co..... 56, 106, 704
American Oxygen Co..... 105, 110, 166
American Peat Society..... 438
American Platinum Works..... 110
American Regenerator Co..... 111
American Rolling Mill Co..... 98, 225
American Vanadium Co..... 214
Amethyst coloration of crystal glass. (S.) 697
Amethyst mill *677
Ammonia-Cyanide Engineering Co. 214
Ammonia, Synthesis 539
——Haber and Le Rossignol. 308
——Blackmore. (P.) 604
Ammonia gas, Specific heat and chemical equilibrium. Nernst (S.) 206
Ammonia-cyanide process. Mosher (S.). 286
Ammonia-soda process. Olson (S.) .. 151
——Mallet-Bordeaux 300
Ammonium sulphate. Smith. (S.) 502
Analyses
aluminium and alloys. Seligman and Willott (S.) 95
——Calorimetric of hydrated salts 6
——Chromium in steel. Randall 17
——Clays 283
——Copper. Buskett. (S.) 361
Grading analyses. Stadler (S.) 50
Manganese bronze. Swan..... 463
Screen analysis 632
——Tin. Gray. (S.) 426
——Transferous iron ores. Brown 616
——oleomargarine blue 281
——Water in petroleum..... *93, 111
——zinc retort residues 66
——(See also Electroanalysis.)
Andrew, F. A. S..... 162
Annealing furnace. Automatic. Biever . *618
Annealing furnace. Rockwell (P.) 98
Anode. Rotating graphite. Turrentine . 340
Anthony Company 117
Anthony, H. M. Co 604
Antimony, Arsenical antimony ores treatment. Herrenschmidt (P.) 90
Antimony-lead alloys. Ewen and Turner (S.) 641
Antimony-lead ores smelting. Hall 86
Antiquarian Library *91
Arcall, Ph. 1
Arc furnace. Dewey. Pastor 12
Arsenical-cobalt-nickel ores. Treatment. Cito *141
Arsenic-copper alloys. Bengough and Hill. (S.) 95, 141
Arsenic, Native arsenical silver ores. Dewey (P.) 161
Assay of gold alloys. Smith (S.) 92, 145
Assay values. Standardization 411
Astatine. Tames 47
Atlas Power Co..... 196
Atmosphere, Oxygen section. See Nitric Acid from air, also Carbide from air, also Ammonia synthesis.)
Atomic weight of valence. Hostetter 200
Averaging instrument for circular short records *440

B

BADGER, E. B. & Sons Co..... 158
Backeland, L. H.....310, 328, *329, 658
Bakelite 310, 328, 647
Balls, Steel. For burnishing..... 600
Bancroft, W. D..... 658
Banks, J. H..... 605
Barium hydroxide and chlorine by electrolysis. Clemm. (P.)..... 647
Barrel. Tumbling. For burnishing with steel balls *600
Bartley Jonathan, Crucible Co..... 438
Basic bessemer process in Germany. Esser *484
Basicity. Relative of metals. Kahlenberg. 638
Baskerville, Chas. 658
Bauxite, French 109
Bauxite refining. Saunders. (P.)..... 431
Bauxite refractory 107
Beam, T. W..... 304
Beauty in science and art..... 609
Beeler, H. G..... *231, 553
Berg, E. J..... 112
Bessemer Gas Engine Co 581
Bessemer process, basic, in Germany. Esser *484
Bessemer roasting 222, 317
Bethlehem Steel Co. New blast furnace, ... *318
Benson, H. K 605
Bettles, A. J..... 216
Bicarbonate of soda by electrolysis. Finlay (P.)..... 548
Bickford Firebrick Co..... 304
Bigelow, W. D..... 658
Birkeland, Kr. Biography and portrait.. *451
Birkenstein, S., & Sons..... 438
Bismuth, Refining. Foerster and Schwahe. (S.) 427
Bismuth-lead smelting. Bretherton. (S.) 363
Black sands treatment. Alexander..... *3
Blast Furnace:
——Advantages of enriched air blast. Richards 123
——Andrew & Hitchcock Iron Co..... 215
——Calculations on reactions in. Brown. 663
——Causes of non-uniformity of operation. Cook 251
——charging apparatus. Collord. (P.).. 504
——Kennedy. (P.) 547
——(copper) charges calculated. Barbour. (S.) 43
——Decomposition of carbon monoxide. Zimmermann *182
——Dry blast. Rationale of Richards. 481
——Feeding device. Dwight. (P.) *600
——for zinc-iron ore. Gordon (P.) .. *689
——gas. Hislop on Wysor and Brown 303
——gas cleaning. Morean (P.) *431
——gas scrubber. Steinhart. (P.)..... 594
——Gayley's dead working. Richards. 433
——Hot blast and dry blast. Wüst..... 481
——Irregularities of running..... 221
——Material and heat balance sheet. Gulbransen 482
——New of Bethlehem Steel Co. Landis *318
——Operation. Non-uniformity. Sweetser 315
and Baker 316
——operation. Uniformity. Richards .. 58
——Oxygen blast 63
——Pressed without dry blast. Sweetser. 315
——slag for cement. (S.) 168
——Spectroscopic examination. Passaw . *481
——slag for glass tiles and slates 91
——Slag. Utilizing heat of. Vautin. 290, *691
——Turbo-compressors for. Rateau 480
Blast roasting. Hofman. (S.) 545
Blast, centering. Moore 317
Bleaching liquor. (See Hypochlorite.)
Blowers. Positive *608
Blowholes. Closing and welding in steel ingots. Howe 630
Blowpipes for welding 109
Boldington, H. D 605
Bowers, M. T 228, 658
Boiler cleaning devices 604
Boiler efficiency and smokeless combustion. Bement (S.) 45
Boiler feed water treatment. Bashore 20
Boilers. Decomposition of soda in steam boilers. (S.) 805

Boiler plants. Recording velocity gauges. Hymans *299
Boilers. Mechanical draft for 604
Boiling points of metals. Greenwood... 203
Bonnot Co. 604
Book Reviews:
——Acheson. A. Pathfinder 654
——Ashcroft. Study of electrothermal and electrolytic industries 306
——Baskerville. General inorganic chemistry 58
——Baskerville and Curtis. Laboratory manual 58
——Bottler. Lack and Firniss-Fabrikation 114
——Brown. Modern assaying 442
——Byron and Christopher. Modern cooking practice 218
——Cirkel. Iron ore deposits along the Ottawa and Gatineau rivers.... 381
——Clennell. Chemistry of cyanide solutions 218
——Cramp and Smith. Vectors and vector diagrams 382
——Cushman and Gardner. Corrosion and preservation of iron and steel 382
——Desch. Metallography 442
——Finlay. Cost of mining 114
——Frazer and Brown. Tables for determination of minerals 442
——Fulton. Principles of metallurgy... 654
——Gibson. Romance of modern manufacture 306
——Groth. Welding and cutting metals. 169
——Journal of the Municipal School of Technology 654
——Klar. Technologie der Holzverkohlung 706
——Manville. Les deconvertes modernes en physique 114
——Mayer. Die Warmetechnik des Siemens. Martinofens 554
——Mechanical World Electrical Pocketbook 113
——Mechanical World Pocket Diary for 1910. 113
——Mineral Resources of U. S. 1908.. 306
——Musu-Boy. Lo zinco 58
——Nagel. Producer gas-fired furnaces.. 217
——Newell. Course in inorganic chemistry 58
——Nikaido. Beet sugar making..... 170
——Noyes. A text book of organic chemistry 606
——Panayeff. Die wichtigsten seltenen Erden als Keasentien..... 381
——Peckham. Solid bituminens..... 169
——Peddle. The construction of graphical charts 606
——Philip. Romance of modern chemistry 306
——Pick and Conrad. Production of ferrosilicon in electric furnace.... 218
——Rengade. Analyse thermique et metallographie microscopique..... 114
——Richards. Textbook of ore dressing. 169
——Auer. Elements of metallography.. 58
——Stevens. Copper handbook 306
——Tower. Qualitative chemical analysis. 170
——Transactions of the American Institute of Chemical Engineers..... 510
——Welcome photographic exposure record 58
Booth Apparatus Co. 604
Borates. Use in reduction of refractory metals. Girod 539
Boron for cast copper of high electric conductivity. Weintraub 629
Boron steel for transformer sheets. Whitney. (P.) 288
Boston Belting Co. 304
Braschi, V. M. 705
Brass for cartridges. Grard. (S.)..... 94
Brass foundry. Metallography in. Primrose *561
Brass foundry. The chemist in. Corse. 265
Brass. Heat treatment. Bengough and Hudson 640, 643
Brass loco-tubes. Failure. Hughes. (S.), 94, 145
Brass. Peck and Hodgkinson. (P.)..... 209
Brazing plant. Hart *54
Brazing. Reinforced. Swaney..... 300
Bringham, W. G. 167
Briquetting ore. Franke..... 480
——Glass. 431
——Shaw. (P.) 547
Briquetting machinery 166
Bristol Co. 379, *440, 509
British Aluminium Co. 495
British Association 589, 639
Bromide electrolysis. Foerster and Yamasaki. (S.) 427
Bronze. Phosphor. Hudson and Law. (S.) 95, 145
Brown, A. A. 112
Brown, Favette 168
Brown Hoisting Machinery Co..... 109, 214
Brown Instrument Co. 304, 509, *703
Browning, Victor R., & Co. 437
Brunton, D. W. 304, 605
Brushes. Carbon-silicon. Egly. (P.).. 101
Buckeye Engine Co. 111
Buckley, E. R. 653
Bullion and assay values. Standardization 118
Bureau of Mines 383, 474
Bureau of Standards. Analyzed samples, 118, 438
Burgess, C. F. 470, 658
Burners for gas 166
Burnings on *102
Burnishing. Tumbling barrel with steel balls *600
Butte district. Copper precipitation..... *614

C

CAETANI, G. 653
Calcium. Electrolytic preparation. Frary, Bicknell, Trouson 631
Calcium. Electrolytic preparation. Johnson 631
Calcium-aluminium alloys. Breckenridge. 349
Calcium Carbide:
——Frouch. (D.) 380
——Hartenstein. (F.)..... 99, 597, 602
——Hewes. (P.) 602
——Meyer and Stillesen. (P.) *548
——Patten. (D.) 380
——Perkin. (S.) 287
——industry in Europe. (S.)..... 96
——Equilibrium of the system of lime, carbon, carbide and carbon monoxide. Thompson *279, *324
——patent law suit. Outcome..... 467
Calcium Cyanamide:
——Foerster and Jacoby. (S.)..... 47
——Meyer and Stillesen. (P.)....*548, 692
——Perkin. (S.) 287
——Calcium cyanamide equilibrium. Thompson and Lombard...*617, *682
——in France 589
——at Westeregeln 539
Calcium nitrite. Acker. (P.)..... 50
Calcium silicide for steel refining. Strauss. (P.) 150, 546
——Willson and Hall. (P.) 596
Calcium-zinc. Seward and Kügelgen. (P.) 99
California smelters 611
Callbreath, J. F., Jr. 510
Calorimeter. Automatic gas *212
Calumet Engineering Works..... 437
Cameron, F. K. 658
Camp Bird 603, 626
Camp, J. M. 510
Canada. Mineral resources and waterpowers. Mortimer-Lamb 476
Canadian Copper Co. (S.)..... 425
Canadian Mining Institute 109
Canada Consolidated Copper Co..... 441
Cananea. Improvements at 514
Carbides in manganese steel. Arnold and Read 419, 422
Carbon cells 384
Carbon dioxide recorders..... 214
Carbon electrodes for electrolysis. Stubs. (P.) 152
Carbon graphitized. Tone. (P.)..... 432
Carbon monoxide. Decomposition in presence of catalytic agents. Zimmermann 171, *182
Carbon-silicon brushes. Egly. (P.)..... 101
Carborundum Co. 438
Carborundum. Purification. Higgins. (P.) 597
Carborundum. Tone. (P.) 148, 548
Carnahan, R. B., Jr. 605
Carnegie Steel Co. 356, 358
Carpenter, F. R. 305
Cartridge brass. (S.) 94
Carbon refractory 107
Case hardening. Giesen. (S.)..... 284
——Grayson. (S.) 361
——Guillet. (S.) 542
Cassiterite. Tin from. Scott. (P.)... *429
Castings. Repair. Lamberton. (P.).... 102
Castings. Sinking heads. Kennedy.... 497
Cast Iron Brazing Co. 55
Cement. Constitution. Levy..... *531
Castner Electrolytic Co. 215
Castner & Kellner Alkali Co. 40
Cates, L. S. 510
Cathode for diaphragm cells. Sperry. (P.) 433
Cement from slag. (S.) 152
——Microscopic examination. Passow, *483, 596
Cement. Increased use 583
Cement kiln. Rotary. Fuel requirements. Landis 526
Cement. Le Chatelier boiling test..... 282
Cement. Portland 589
Cement plaster from gypsite..... 610
Census of electric central stations..... 441
Central Foundry Supply Co. 437
Centrifuges 166
Centrifuge for slime estimation..... 604
Ceramic works electroplating. Heller. (P.) 367
Chain Belt Co. 215
Chandler, C. F. 65, 174, 321
Charcoal precipitation for cyanide or chloride solutions. Edwards. (P.) 595
Charge of ions. Millikan..... 638
Checkerwork for Siemens-Martin furnaces. Friederich *480, 517
Chemical engineering. Study of materials as a subject in a course in. McKenna 456
Chemical industries of U. S. Munroe, 172, 196, 267, 320, 321
Chemical industry. Problems in. Baker. (S.) 499
Chemists' Building..... 4, 64, 226, *701
Chesterton, A. W., Co. 214
Chilian mills, slow-speed..... 166
Chlorates. Electrolytic production. Muller and Buchner. (S.)..... 153
——Bates and Adams. (P.)..... 100
Chlorides of refractory metals. Reduction. Pring and Fielding..... 39
Chloridizing roasting of cuprous pyrites cinders. Lilja. 395
Chlorination and charcoal precipitation. Clark. (S.) 425
Chlorination of refractory ores. Koebler. (P.) 49
Chlorine and barium or strontium hydroxide. Clemm. (P.)..... 647
Chlorine in cyanidation of silver ores. Mosher. (S.) 424
Chlorine. Electrolytic at Mount Morgan. Du Faur. *575
Chlorine. Liquid..... 215, 704
Chromium. Determination in chrome and chrome nickel steel. Randall.. 17
Chromium-cobalt alloys. Haynes..... 652
Chromium-copper alloy. Naulty and Scanlin. (P.) 690
Chromium steel. 419
——McWilliam and Barnes. (S.) 424
Chromite refractory 107
Circular chart records. Averaging instrument 440
Classification and the tube mill circuit. Smart *271
Classification. Pulp. Sherrod..... *139
Classifier. Henderson *321
Clays. Analysis 283
Cleaning blast furnace gas. Morgan. (P.) *431
——Carrier. (P.) 694
——Hickey. (P.) *694
——Morgan 431
Cleaning metal articles. Hambuechen. 634
——Kalye 604
——Manley. (P.) 292
——Phillips and Hambuechen. (P.).... 101
Coal briquetting 166
Coal. Buying on specification..... 379
Coal storage. Porter and Ovitz. (S.).. 206
Coal. Volatile matter in. Porter and Ovitz 649
Cobalt-chromium alloys. Haynes..... 652
Cobalt district. Ore dressing..... 515
Cobalt, New markets for..... 557
Cobalt-nickel-silver-arsenic ores. Cito. (P.) 148, *341
Coblentz, V. 658
Coke. By-product coke oven plant of Bethlehem Steel Co. 226
Coke. Connellsville practice and by-product coking..... 117
Coke-oven by-products. Recovery. Ran. 478
Coke-oven gas for open-hearth furnaces. Terpitz 488
Coke ovens. Herbst 477
Coke specifications for foundries. Moldenke 400
Coking, by-product, and Pittsburgh..... 222
College of the City of New York..... 5
Colorado Gold Mining & Smelting Co.. 610
Colorado Iron Works Co. 214, 662
Colorado mining industry..... 660
Colorado. Precious metals in..... 163
Colorado School of Mines..... 271, 388
Combustion, smokeless, and boiler efficiency. Bement. (S.)..... 45
Commission of Conservation of Canada.. 439
Compressors. Centrifugal air compressors for oil burning *213
Compressors. Hydraulic air. Bernstein. 480
Compressors. Turbo, for blast furnaces. Rateau 480
Concentration of Ores:
——argentiferous lead ore. Palmer. (S.) 498
——Canadian testing plant for concentration of materials 652
——Concentrating machinery 215
——Concentrating table. Eccleston..... *602
——Concentrating table. Wilfley. Extension of riffles 379
——Concentrator. Blake. (P.)..... *500
——Dry ore concentrator. McKesson... *549
——Electrostatic. Newell. (P.)..... 210
——Electrostatic. Huff 215, *295
——Electrostatic. McGregor 636
——Elmore vacuum concentration at Sulitelma. (S.) 425
——Fine sand on belt vanner. Owen and Stephen 525
——Flotation processes..... 201, 205, 498
——Lead-silver ore. Caetani. (S.)... 544
——Magnetic separator. Cleveland-Knowles. 215
——Ore dressing in Cobalt district..... 515
——Removal of scrap iron and steel from ore 379
——Removal of iron from ore pulp. Brown. (S.) 642
——Removal of wood from mill ore.... 379
——Status of ore dressing. Bodenstein. 477
——Tin dressing in Tasmania. (S.)..... 591
——Zinc-lead. Midvale. (S.)..... 287
——Zinc ore dressing in Colorado. Parmelee *568, *620, *677
Concentration of sulphuric acid. Lüttgen. (S.) 97, *266
Concrete. Action of sewage. Chambers. 360

Concrete Reinforced for stamp mills. Robertson. (S.) 642
Concrete vats and tanks. Meyer 702
Condensers. Nagel *551
Condenser for smoke and gases. Merrick. (P.) *430
Condensers. High-vacuum surface for steam turbines 380
Conductivity apparatus for controlling purity of water 540
Conductivity Thermal. Hering....612, *647
Conductors. Heavy alternating-current for furnaces. Randall 331
Conglomerating iron ore in electric furnace. Ruthenburg. (D.) 654
——(See also Briquetting.)
Congress. Eighth International for Applied Chemistry, 1912.....115, 118, 586, 610, 658
Congress, International, of Inventors.... 175
Congress, Fifth International for Mining and Metallurgy at Dusseldorf, 1910 *475
Conical tube mill. Crushing in stages. Hardinge *599
Conservation of natural resources. Finney. 355
Conservation and the chemical engineer. S. P. Sadtler 9
Consolidated Mercur 610
Consolidated Nickel Co. *277
Constitution of cast irons and carbon steels. Levy *531
Continental-American Ore Co. 109
Converter. Basic-lined converter for copper 388, 498
——Copper. Murphy and Culley. (P.) 688
——for bessemerizing copper matte. Peirce. (P.) 48
——copper. Schroder. (S.) 590
——Vortex copper Haas. (S.) 426
——(See also Iron and Steel, Copper, etc.)
Cooling curves. Graphic recorder. Thwing *367
Co-operation and business stability in the iron and steel industry. Gary.. 613
Copper
——Alloys. (P.) 367
——Alloys. Peck and Hodgkinson. (P.). 209
——Analysis. Buskett. (S.) 363
——Aluminium-manganese alloys....154, 202
——Arsenic alloys. Bengough and Hill. (S.) 95, 144
——Basic-lined converter 388, 498
——Bessemerizing copper matte and copper-nickel matte. Broom. (S.). 425
——Calculation of blast-furnace charges Barbour. (S.) 43
——Cast copper of high electric conductivity. Weintraub. 629
——Chemical treatment of copper ores. Greenawalt. (P.) 644
——Chloridizing roasting of cuprous pyrites cinders. Lilja *395
——Chromium alloy. Naulty and Scanlin. (P.) 690
——Clark interests 388
——Converter connection. Peirce. (P.) 48
——Converter. Murphy and Culley. (P.) 688
——Converting high-grade matte. Longbottom. (S.) 426
——Converting. Schroder. (S.) 590
——Copper slags in electric furnace. Wright 204
——Down-draft furnace. St Seine. (P.) 367
——Effect of impurities on copper. Johnson. *570, 640
——Electric smelting of copper ores. Ladd 7
——Electrolytic refining at Lithgow (S.) 498
——in Australia. Snyder. (S.). 426
——the cyanide solution. Thompson and Hamilton 347
——Eliminating lead from matte and ore Mannheimer (P.) 429
——Electric vacuum concentration at Sudbury. (S.) 425
——Fractional roasting and flotation. Ramage. (P.) 146
——Hot-blast smelting. Mace *671
——Impurities in tough-pitch copper containing arsenic. Johnson. (S.) 641

Ourselves.

Seven years ago this journal was founded as "Electrochemical Industry," to be the exponent of electrochemistry and its industrial applications. It has grown as these branches have developed, has put forth its best endeavors to represent every phase of this development, and will increase rather than relax in its future service to this great field of professional and industrial activity. Owing to the overlapping of, and the interrelations between, the different branches of chemistry and metallurgy, however, it was early necessary to enlarge the scope of the editorial policy so as to include more broadly the industrial applications of chemistry and metallurgy, and more particularly those of an engineering nature. This evolution first found expression in the change of name from "Electrochemical Industry" to "Electrochemical and Metallurgical Industry" in 1905, and a further step was the absorption of the "Iron and Steel Magazine" in 1906. The change of name now announced to "Metallurgical and Chemical Engineering" is the final consequence of the logical development of the past seven years, for the new title defines precisely the field which this journal has been more and more making its own in its past career. The adoption of the new name brings us privileges and lays upon us obligations—the privilege of addressing more generally than before all men interested in the engineering features of metallurgy and chemistry, and the obligation of living up to our responsibility to cover as completely as possible all important phases of these broad fields.

* * *

The work to be done is well defined and the field is not covered by any other journal. We do not address the purely mining engineer on the one hand nor the purely analyst on the other. In brief, all our efforts will be concentrated on making the best possible journal to serve the metallurgical and chemical sides of engineering. There is a natural community of interest between the metallurgical and the chemical engineer. Managers and engineers of ore concentration plants, of cyanide works, of metal smelters, of refineries, as well as manufacturing chemists and chemists engaged in engineering practice in industrial establishments of all kinds, are all more or less interested in the same processes—in crushing and grinding, concentration and separation, drying and evaporating, filtration, calcination, combustion, furnace operation, fusion, welding, in the measurement and control of temperatures, in chimney draft and forced draft, and in a hundred other lines of work. By making the word "Engineering" part of our new title, we wish to emphasize the fact that this journal is not, on the one hand, a trade paper, nor, on the other hand, a periodical representative of pure science. While neither commercial news nor scientific articles or abstracts will be absent from our columns, they will be secondary to the record and discussion of what is primarily needful in the work of the engineer or in the conduct and management of metallurgical and chemical works. Naturally, in these days when electrochemistry is extending more and

more in its scope and in its relations with other branches of metallurgy and chemistry—we need mention only the electric refining furnace in the steel industry and the fixation of atmospheric nitrogen in the manufacture of fertilizers and explosives—it will be our duty and our privilege to be as jealous an exponent of electrochemistry in all of its phases as ever. This is our birthright, which we do not relinquish by change of name. But along the broader lines above sketched, we feel convinced that this journal can be made a powerful catalytic agent in the advance of metallurgical and chemical engineering; and we sincerely hope that in our efforts to the attainment of this end, we may count on the support of all interested in the cause in which these pages are enlisted.

Again the Problem of Electrode Losses

The interesting article by Dr. J. Forssell of Sweden, published in this issue, had been written before the author had seen the article of Mr. Hering in our October issue and the papers on the same subject, presented at the last meeting of the American Electrochemical Society, and published in our December issue. This explains the omission of references to these publications in Dr. Forssell's article. While the treatment of the subject by Dr. Forssell has various original features, it is particularly interesting on account of the way in which he takes account of the heat leakage from the electrodes into the wall. He lumps this together with half the Joulean heat loss and introduces into his formulas a coefficient which may vary from ½ to 1 according to conditions. The method is feasible. But to get a simple conception of what really happens, it is perhaps preferable to consider the matter in the following way, the results being easily proven by analysis, at least under simplifying assumptions. We can consider the whole heat loss as a superposition of three phenomena. Firstly, we have the simple heat conduction, due to temperature difference at the two ends; this is the heat H that would flow if there was no electric current. Secondly, we have the Joulean heat i^2r. Thirdly, we have the heat leakage L from the electrode into the surrounding wall. The Joulean heat flows off impartially to both sides, ½ i^2r into the furnace and ½ i^2r into the water jacket outside. The heat L which is given off from the electrode to the surrounding walls is also derived impartially in equal halves from both sides, ½ L from the interior of the furnace and ½ L from the water jacket. The heat which flows from the furnace into the hot electrode end is, therefore, $H - ½ i^2r + ½ L$. The heat which goes into the water jacket is $H + ½ i^2r - ½ L$. But this latter quantity is not the whole electrode loss, since the latter includes that heat which is given off from the electrode to the furnace walls. If this goes completely to the outside, the total electrode loss is $H + ½ i^2r + ½ L$. Further advance must now be made experimentally. It would seem advisable to determine the "constants" for carbon and graphite under conditions which exclude heat leakage into the wall (by some such method as Mr. Hering's, described in our December issue) and then to determine afterwards the effect of leakage for various furnace designs and electrode constructions.

The Situation in the Iron and Steel Industry

The iron and steel industry has closed a spectacular year. The trade movement has shown remarkable swings as to prices and as to tonnage. With three years of heavy demand and gradually advancing prices, followed by a 15 months' campaign to maintain prices of finished steel products in the face of greatly reduced demand, the market broke Feb. 18, 1909. Perhaps it is more accurate to say that on that date the decision was reached by officials of the United States Steel Corporation, in conference with representatives of some of the important independent interests, to throw the market open, and that thereafter different portions of the price structure collapsed one at a time. Within two days of the decision steel bars suffered a reduction of $4 a ton and plates and shapes a reduction of $6 a ton. One business day later, Feb. 22, steel pipe was reduced five points, or about $9.50 per ton, and two days thereafter sheets dropped $4 to $5 a ton. On March 15 tin plate was cut 25 cents per box. Wire prices were moderately well held to give jobbers an opportunity to distribute their stocks, and on May 1 cuts were made of $7 a ton on nails, $8 on plain wire and $10 on barb wire. In steel pipe, tin plates and wire products the initial cuts were found sufficient to meet the situation, while in bars, plates, shapes and sheets the first cuts were followed by shading which established new low points. There was no cut in standard sections of rails. The subject was canvassed at the time the market on other finished steel products was thrown open, and it was concluded that no large business would follow a reduction. In succeeding months individual manufacturers stood ready to make a sharp cut in rails, if it appeared that large orders could be secured thereby, but it was evident that the railroads were not prepared to buy rails heavily. In no line did it require a long time to develop a bottom. Bars, plates and shapes were trending upward within a little over two months from the time of the original cut; tin plates and pipe did not advance until long after their reductions, but in each case there was but one reduction, the market being held firm thereafter. The lowest prices on wire products were open for a single fortnight, the reductions being made May 1 and the first advances May 15. Sheet products were slowest to find a stable basis, but there was double delay in that case; prices of sheets were reduced Feb. 24, but there was a long delay before the steel mills made their lowest prices on sheet bars; when the minimum on sheet bars was finally reached the independent sheet mills loaded up and fresh cutting occurred in their finished product, and it was not until July that sheet prices showed a discernible tendency to advance.

* * *

Of the wisdom or unwisdom first of the price-maintenance movement and then of its abandonment, *quot homines, tot sententiae*. The game was played with such pomp and circumstance that the sudden abandonment could not but shock the aesthetic senses of the onlookers. Those who had been nearer the stage had heard the creaking of the machinery and had felt that the play was being carried on partly to amuse the audience and partly to keep the players out of mischief. If the undertaking was as serious as its sponsors maintained during its progress, the disruption of the forces should have been regarded as a calamity, but the event has proved what was maintained by some observers at the time, that a definite break would be followed by a rapid recovery. Price maintenance, as has been pointed out before, was no new thing in the steel industry, on many occasions there had been efforts in that direction. The trappings, however, were new. The break has proved to be but

an incident in history. Substantially the entire reduction in finished steel products was recovered by the subsequent advances, except in the case of pipe. Most finished steel products closed the year at prices $1 to $2 a ton below the opening prices, but the closing prices were firmly maintained, while the opening prices were largely nominal, and subject to shading. Merchant steel pipe, however, is a conspicuous exception, as it experienced but a small recovery.

* * *

No less spectacular than the movement in prices has been the movement in tonnage. It strained the capacity of existing plants to make 23,000,000 tons of pig iron in 1905; next year under similar strain the increased capacity produced 25,300,000 tons; in 1907 the industry, still pushed with increased capacity, was making for an output of about 27,350,000 tons and had reached a rate closely approximating 28,000,000 tons in October, but the panic of that month caused a sudden slump and the calendar year's output was only 25,781,361 tons. In January, 1908, the rate of output had dropped below 13,000,000 tons, yet at that time there were new furnaces in course of erection with an annual capacity of 3,500,000 tons. Where was the hope that capacity would again be fully employed, in any reasonable period of time? The year 1908 gave no answer, for its total output fell below 16,000,000 tons, but the year 1909 showed the wonderful resources of this prince-and-pauper industry. It opened with a rate of 21,500,000 tons, showed an average rate of 22,000,000 tons during the first half, and closed with a rate of nearly 32,000,000 tons. With the present rate of production the physical capacity has been closely approximated. There are a number of old furnaces not yet in blast, and several new ones shortly to be completed; apparently there is perhaps 2,000,000 tons of capacity left to come in, but practically the present rate is a fictitious one. Many blast furnaces were relined and otherwise repaired during the depression, and the efficiency of the furnaces as a whole is at present abnormally high. It is normal for close to 10 per cent of the furnaces to be out from one cause or another, but at the moment the idle capacity, including furnaces not completed, is less than 10 per cent of the capacity in blast. It is improbable that the existing plant could steadily make 32,000,000 tons a year. With the new furnaces, some nearly completed and some only projected, a capacity of 33,000,000 tons or more is easily in sight.

* * *

We have been dealing with pig iron. Of the 25,781,361 tons made in 1907, the record calendar year, about 18,000,000 tons went into steel. The gain in pig iron, from a maximum rate in 1907 of nearly 28,000,000 tons a year to a rate of nearly 32,000,000 tons a year at the close of 1909, was almost wholly in steel-making iron. The foundry trade lagged behind in the industrial revival, as it usually does, the trade dictum being that the foundry industry is six months behind the steel industry in such cases. That practically the entire gain should be in the steel industry is remarkable, as the percentage of gain is increased, but it is still more remarkable to observe that rail production has fallen behind, and consumption of plates and shapes in the steel-car industry has certainly made no gain over 1907. The gain in the total, plus an amount to cover these defections, must be found in other lines of consumption. It does not seem that there has been a gain in bridges and buildings. There must be an enormous gain, on the other hand, in the light lines, pipe, wire, sheet products, merchant mill products, etc.

* * *

When the steel industry of the United States confined itself almost exclusively to the Bessemer process, pig iron production was a close index to finished steel production. A given tonnage of Bessemer pig iron being produced, the metalloids were eliminated and a little iron lost, most of the scrap made in casting and rolling went back into the converter, and the finished Bessemer steel was regularly a small percentage below the original pig iron production. Nowadays the case is complicated by the open-hearth furnace, with its scrap and ore additions, some of the scrap being old material but the bulk of it new material produced in Bessemer and open-hearth steel works. We know that in 1909 practically the same tonnage of pig iron was produced as in 1907, and that there was considerably more steel-making pig iron and considerably less foundry iron and other grades. We know, too, that the Bessemer steel works did not do as well in 1909 as in 1907, and hence we are perfectly safe in concluding that, the acid open-hearth being a minor issue, the basic open-hearth furnaces consumed a great deal more basic pig iron in 1909 than they did in 1907, but what good does that conclusion do us as an index to steel production? In past years the production of basic open-hearth steel ingots has been roughly double the production of basic pig iron. If each additional ton of pig iron in 1909 was used with an additional ton of scrap, the gain in steel production was very large, especially since there was less new scrap to be drawn from Bessemer plants. Old material, however, was scarce in 1909, as shown by market prices compared with pig iron, and it may be that some of the additional pig iron production was for the purpose of making up for the shortage in scrap, in which case we should find a much smaller gain in steel output. The official statistics will be awaited with unusual interest. Perhaps the best that can be said at this time is: In 1907 we made 25,781,361 tons of pig iron, the calendar year record, and in 1909 we made substantially the same tonnage; in 1906 we made 12,275,830 tons of Bessemer steel ingots and castings, the record; in 1907, 11,667,549 tons; in 1909, probably considerably less than 11,000,000 tons; in 1907 we made 11,549,736 tons of open-hearth steel ingots and castings, the record; in 1909, probably more than 13,000,000 tons; in 1907 we made 17,664,736 tons of finished rolled steel, the record; in 1909, probably half a million tons either way from 19,000,000 tons.

* * *

The pinch of an insufficient scrap supply noted in the foregoing has not been without its effect in the selection of processes for the future. Late in the year the Bethlehem Steel Company, having before it alternative propositions of adding to its Saucon plant of ten 50-ton basic open-hearth furnaces either 10 similar furnaces or two 20-ton Bessemer vessels for duplexing, chose the latter; the Jones & Laughlin Steel Company experimented with duplexing by combining its Bessemer and open-hearth equipment, originally built with no such idea, and the United States Steel Corporation, which originally made authorizations for the Gary plant, involving an open-hearth ingot capacity more than double the blast-furnace capacity, has been considering duplexing and the addition of blast furnaces without corresponding open-hearth additions.

Perkin Medal.

At the meeting of the Perkin medal committee on Monday, Dec. 13, at the Chemists' Club in New York City, in which delegates of the Society of Chemical Industry, the American Chemical Society and the American Electrochemical Society participated, the Perkin medal for 1910 was awarded unanimously to Dr. Edward G. Acheson, of Niagara Falls. The formal award will be made at the January meeting of the New York Section of the Society of Chemical Industry.

Boston Meeting of the American Chemical Society.

The forty-first meeting of the American Chemical Society is to be held in Boston in the last week of December. It will begin on Monday, Dec. 27, and last to Friday, Dec. 31. Special arrangements have been made for the entertainment of the visitors, while the program for professional papers to be presented before the different Sections contains not less than 111 papers. Of these there are 60 to be presented before the Division of Industrial Chemists (Mr. A. D. Little, chairman). Before the same section there will also be presented a symposium of papers on the chemistry of paints.

Of lectures of general interest we note the report by Dr. F. W. Clark for the International Committee of Atomic Weights, a paper by Dr. T. W Richards on methods employed in precise chemical investigations, a paper by Dr. Louis Kahlenberg on the past and future of the study of solutions, and the address of the retiring president of the American Chemical Society, Dr W R. Whitney, on "Some Chemistry of Artificial Light."

Dr. C. L Parsons, Durham, N. H., is the secretary of the society

Annual Meeting of the Western Association of Technical Chemists and Metallurgists.

The fifth annual meeting of the Western Association of Technical Chemists and Metallurgists will be held at Boulder, Golden and Denver on January 6, 7 and 8, 1910. There is an interesting program of papers and a number of visits have been arranged by the local committees to various industrial plants, including smelters, beet sugar factories and breweries. The various laboratories of the State University and the State School of Mines will also be visited.

Mr H C Parmelee, 1510 Court Place, Denver, Colo., is the secretary of the association.

Philadelphia Meeting of the American Institute of Chemical Engineers.

The second annual meeting of the American Institute of Chemical Engineers was held in Philadelphia from Dec. 8 to 10 and the attractive program, which was printed in our last issue, was successfully carried out. The attendance at the meetings and numerous excursions and at the dinner in the Hotel Walton was very satisfactory.

The address of the retiring president, Dr S P Sadtler, on the relation of the chemical engineer to the conservation problem is printed in full on page 9 of this issue, while abstracts of some of the papers presented will be found in the Synopsis in this issue. Of other papers presented we note one by Mr E R Taylor on the electric furnace for smelting iron ore, which covered in a new form essentially the same ground as his Electrometallurgy paper published in our last issue

The following officers were elected for next year: President, Dr Chas F McKenna; vice-presidents, Dr F W Frerichs, Dr Edward G Acheson and Dr Eugene Haanel, secretary, Dr John C Olsen, Pratt Institute, Brooklyn, N Y; treasurer, Wm M Booth; auditor, H D Reynard; directors, G B Adamson, D Wesson, Dr F Goldmann, L Reuter, Thorn Smith, H F. Brown, Dr. W. M Grosvenor, R K. Meade, Dr S. P. Sadtler.

Dr. Chas. F. McKenna, the newly elected president of the American Institute of Chemical Engineers, is a new Yorker by birth, 48 years of age, an M.A. of St. Francis Xavier's College and a Ph.D. of Columbia University. He was chairman of the committee of six which organized the Institute and has been first vice-president since its organization.

His earliest work in chemistry was with the Havemeyer Sugar Refining Company and the Cambria Steel Company.

In 1887 he designed, erected and operated a plant for the manufacture of lime for the purification of gas, and this led him first into the study of the utilization of lime wastes and later into the field of limes, mortars and cements, in which he has won a high reputation. In the manufacture of Portland cement he has acted for many of the manufacturers in the study of their raw materials and design of plants.

In the beginning of his work as a consultant and chemical expert he was associated with Dr. Gidson E. Moore and established a testing laboratory of which he is still the head and which has aided him to attain a position of authority upon materials their qualities and processes of treatment.

He has been a chemist to several metallurgical and manufacturing concerns and is frequently consulted by the authorities of his own city, while his devotions to the interests of chemistry, chemists and chemical education are well known and generally recognized.

The New Chemists' Club Building.

With great pleasure we are able to state that the preliminary arrangements for the erection of a new large Chemists' Building, worthy of the industry which it is to represent, have been successfully concluded.

The capital of the Chemists' Building Company is to be $250,000, of which $210,000 have been subscribed by nearly 100 individuals or companies. The remainder of the money for the erection of the building will be raised by a mortgage

The directors of the Chemists' Building Company are Dr Morris Loeb, president; Dr Chas. F. Chandler, vice-president; Albert Plant, treasurer; W. H. Nichols, Jr., secretary, Dr Leo H. Backeland.

As already stated, the building is to be erected at 50 to 54 East Forty-first Street, a plot 56 x 100 ft.

The six lowest stories will be devoted to the purposes of the Chemists' Club, while the upper five floors will be used for laboratories.

At the entrance to the club rooms will be a reception room, office and coat room, back of which is a large hall, 50 ft. square, which runs over two stories The front of the second story will be devoted to billiard room, etc. The third story will contain a large social room and the restaurant The front of the fourth story will be devoted to the library, and the back to the board room, a dark room and a chemical museum. On each of the next two floors will be found to bedrooms for club members

It is hoped that the library will be made a thoroughly complete one, and house not only the books of the Chemists' Club, but those of the American Chemical Society and those of the Perkins Fund as well.

The Museum will be devoted to the collection of articles of scientific interest, rather than such as are adapted to popular exhibitions It is also hoped that it will contain specimens of all kinds of chemicals to be used for research in about the same way as a circulating library, that is to say, specimens can be taken out for experiments, or for comparison, on the condition that they be returned or replaced within a given period. The meeting room will be let out to scientific societies and others.

The laboratory floors are to be provided with all the mains necessary to supply the individual laboratories with gas, electricity, water, etc. They are also to contain ventilating flues,

and such provision for hoods that these can be introduced at minimum cost. Indeed, they could probably be provided at once to any tenant who made a lease before the completion of the building. These facilities have been so designed as to make a subdivision of each floor into four individual laboratories with adjacent offices, but, at the same time, it will be easy for a single tenant to make satisfactory use of a whole floor, or half a one.

While the rentals of the laboratories must, necessarily, provide an income for the building, they will be placed at as low a figure as possible, in order that commercial chemists as well as scientific investigators may obtain laboratories at a reasonable cost under far better conditions than those prevalent elsewhere. The advantage will be a fireproof laboratory, with the same improvements that can be found in a modern college building, a central library within reach and those benefits which usually go with the occupancy of a building devoted to a single profession.

Of course, these laboratories can also be rented out for work in cognate sciences, such as physics and biology.

The stockholders have agreed to limit their dividends to 3 percent, and any surplus will be applied to reducing the capital indebtedness of the company. At the same time the Chemists' Club has an option to purchase the entire stock of the company at par within the next 50 years. This will make it possible for the club to purchase the building whenever the capital has been sufficiently reduced by the operation of the provision just stated.

On the other hand, should the club for any reason fail to prosper, the stockholders will have the building, which is always applicable for business purposes, since it is in a central location, and will be constructed in a perfectly satisfactory manner for conversion into ordinary offices.

Municipal Chemistry.

The Department of Chemistry of the College of the City of New York (Prof. Chas. Baskerville, Director) offers during the Spring Semester a course of thirty lectures on the chemistry of daily life.

These lectures will be open to three classes of hearers:

1. Senior students of the college who have complied with the requirements of the department. Laboratory practice (no fees) involving the examination of water, milk, foods, gas, paints and cements, will be had under the direction of Associate Professor Moody.

2. Employees of the city who have studied sufficient chemistry to pursue the laboratory work. The attainments of each applicant will be passed upon individually. The expense involved in apparatus broken and chemicals used must be met by the hearer.

3. A limited number of auditors composed of citizens of New York City will be admitted on applying for a seating to the Director of the department. The last are not admitted in the laboratory part of the course.

The lectures will be given as per printed schedule, at 4 p. m. in the Doremus Lecture Theatre, Chemistry Building, 140th Street and Convent Avenue, Plaza entrance.

All communications should be addressed to the Director, Dr. Chas. Baskerville.

The course of lecture is as follows:

Feb. 4th, Prof. Charles Baskerville, Sanitation.

Feb. 9th, Dr. Wm. P. Mason, Drinking Water and Disease.

Feb. 10th, Dr. Wm. P. Mason, Sources of Municipal Water Supply.

Feb. 11th, Dr. Wm. P. Mason, The Purification of Polluted Water.

Feb. 15th, Dr. Thomas C. Darlington, Milk.

Feb. 18th, Dr. Harvey W. Wiley, The Purpose, Method, and Extent of Food Adulteration.

Feb. 19th, Dr. Harvey W. Wiley, The Remedy of Food Adulteration and Relation of Chemistry thereto.

Feb. 25th, Mr. Bayard C. Fuller, Food Inspection.

March 1st, Mr. Bayard C. Fuller, Spoiled Foods.

March 4th, Dr. Virgil Coblentz, Drugs and their Adulteration.

March 8th, Dr. Virgil Coblentz, Methods for Detecting Adulteration.

March 11th, Dr. Virgil Coblentz, Habit Inducing Drugs.

April 1st, Dr. Allerton S. Cushman, Streets and their Construction.

April 2d, Dr. Allerton S. Cushman, Modern Road Construction.

April 5th, Hon. William H. Edwards, Street Sanitation.

April 8th, Mr. Edward D. Very, Disposal of Ashes and Light Rubbish.

April 12th, Dr. Edward D. Very, Disposal of Garbage.

April 15th, Dr. Edward D. Very, Disposal of Putrescible Materials.

April 19th, Dr. Arthur H. Elliott, Manufacture of Gas.

April 22d, Dr. Arthur H. Elliott, Means of Testing the Properties and Quality of Gas.

April 26th, Dr. Arthur H. Elliott, The Smoke Problem.

April 29th, Dr. Herbert R. Moody, Ventilation.

May 3d, Dr. Thomas A. Storey, The Chemistry of Personal Hygiene.

May 10th, Mr. Maximilian Toch, Paint and Painting.

May 13th, Mr. Maximilian Toch, Corrosion of Metals and its Prevention.

May 17th, Mr. Maximilian Toch, Cement and Concrete.

May 20th, Dr. A. A. Breneman, Combustibles and the Causes of Fires.

May 24th, Dr. A. A. Breneman, Methods of Extinguishing Fires.

May 27th, Dr. N. L. Britton, City Parks, Gardens, and Playgrounds.

The Iron and Steel Market.

December has been a very quiet month in the iron and steel trade, but the market has shown a firm undertone and the lull is regarded as merely the seasonable one which is practically inevitable at this time. No sudden resumption of activity is expected, but a gradual resumption of buying is anticipated as the first quarter is well entered upon, and producers are holding prices of finished steel products firmly, with the tendency to ask higher prices for first half than for first quarter deliveries.

The high pace of production reached in November continued through December. No important additions to capacity were made in the month outside of the blowing in of a few blast furnaces here and there. The iron and steel industry had gotten up very close to the limit of its capacity in October and November, and looked rather for some decrease in output in December on account of weather conditions, but these have been fairly favorable, and the month's statistics are likely to show the best output of the year.

Price changes in December were unimportant, the principal finished steel products being untouched, with the exception that at the close of business Saturday, December 12, a general advance of $1 a ton was made in wire products. These prices apply to jobbers, with whom it is customary to make contracts requiring specifications within 60 days. Specifications on contracts placed at previous prices were not heavy, and the advance was presumably made chiefly with a view of stimulating specifications. Prices had already been made to manufacturers using plain wire at a $2 advance on contracts for deliveries over the first six months of the new year, so that the advanced price to jobbers is $1 a ton below the price made to manufacturers, and another $1 advance to jobbers is expected January 1 or January 15.

Specifications have been heavy on contracts for finished steel products expiring December 31, this applying particularly to steel bar contracts. Such contracts carried prices below the present level, and buyers were anxious to escape having any of the contract tonnage cancelled by the mills at the time limit.

The finished steel trade enters the new year with fully three months of actual operations specified on books in the case of steel bars, and nearly as much specified in plates and shapes. Sheets and tin plates are sold under definite contract involving full half, and perhaps more than half, the prospective production in the first half. Wire and pipe are sold less far ahead, as it is contrary to the policy of the mills to sell for more than about 30 to 60 days ahead.

As a result of the disorder attending the attempt to start the Ætna-Standard sheet plant, of Bridgeport, O., of the American Sheet & Tin Plate Company, it seems to have been decided to abandon all efforts to start the Wheeling district plants. June 30, on the expiration of the annual scale, the members of the Amalgamated Association walked out of all the sheet and tin-plate mills of the American Sheet & Tin Plate Company which had hitherto been union, with the exception of the Guernsey sheet plant, at Cambridge, O., the company having announced that it would operate on the open-shop principle thereafter. Subsequently operations were started at all the sheet and tin plate plants affected, with non-union labor, with the exception of the plants in the Wheeling district, comprising the Ætna-Standard sheet plant at Bridgeport, O., 23 mills; the La Belle tin plate plant at Wheeling, 10 mills, and the Laughlin tin plate plant at Martin's Ferry, O., 23 mills. Wheeling has been a stronghold of union sentiment, and no effort to start operations was made until December 1, when a few mills at the Ætna-Standard plant were started with old workmen, who had requested the management to give them employment. This brought about a small riot, with the calling out of 1500 troops. Cecil A. Robinson, manager in the Wheeling district, has resigned, effective January 1, while D. A. Barrett, superintendent of the Laughlin plant, has been transferred to the Morewood tin plate plant at Gas City, Ind., containing eight mills, which have operated only about one month in the past four years. It is intended to put the Morewood plant in operation, while there appears to be no intention of trying to start any of the Wheeling district plants, at least in the near future.

Statements have been made regarding the building by the Steel Corporation of a large sheet and tin plate plant at Gary, Ind., but it is possible that the announcements at this time are merely an incident of the labor difficulty, since the plans for 50 tin plate and 50 sheet mills for Gary were drawn up more than a year ago. Through the dismantling of a number of sheet and tin plate plants by the American Sheet & Tin Plate Company and the building of a large number of independent plants the Steel Corporation has lost much in relative position, and would not entirely restore its former relations in the industry by building even a 100-mill plant at Gary. The growth of tin plate and sheet consumption has been very rapid, and there is no reason to suppose that demand would not be found for the additional output.

Coke.

Asking prices for Connellsville furnace coke have yielded slightly in the month, to $2.75 or $2.80, but not enough to induce the non-covered furnaces to come into the market on contracts for the new year. During the spectacular advance from less than $2 in July to $3.10 in September a number of contracts were made, two or three small ones being understood to have been made at the top price, but there remains large uncovered requirements. Consumers' expectations seem to be that there will be no collapse, and that there may be a decline. Meanwhile, if they do not make contracts, they can buy prompt coke from time to time.

Pig Iron.

The local pig iron market has been quiet, but prices have been well held. Bessemer is $19, valley, for any delivery, but no important sales have been made since those late in November whereby two subsidiary steel interests took a total of 28,000 tons at this price for the first quarter delivery. Moderate sales of basic have been made for first quarter delivery at $17.25, valley, there being a little tonnage reported as available at $17 for immediate shipment. Foundry iron is $17 to $17.25, valley, depending on delivery, with forge about 75 cents less. Prices delivered at Pittsburg are 90 cents higher than valley. Owing to the offering of speculative Southern iron at $14.50, Birmingham, and then at $14, but only for immediate shipment, the Southern furnaces have yielded from their $15 price and have been ready to do $14.50 for first-half delivery. This price has brought out a moderate amount of business.

Finished Materials.

Prices of finished steel products are very firmly held as below. In cases where a range is indicated, the higher price is for the more extended delivery. Prices are at Pittsburg unless otherwise noted:

Standard steel rails, $28 for Bessemer, $30 for open-hearth, f.o.b. mill, except Colorado.

Plates, $1.55 to $1.60 for tank quality.

Shapes, $1.55 to $1.60 for beams and channels, 15-inch and under, tees, and angles 2 x 3 and larger.

Steel bars, $1.45 to $1.50, base.

Iron bars, $1.70 to $1.75; Chicago, $1.60.

Wire nails, $1.85 base; plain wire, $1.55; galvanized barb wire, $2.15.

Black sheets, 28-gage, $2.40; galvanized, $3.50; blue annealed sheets, 10-gauge, $1.75; painted corrugated roofing, $1.75 per square; galvanized corrugated roofing, $3.

Tin plates, $3.60 for 100-lb. cokes.

The Faraday Society.

The forty-seventh meeting of the Faraday Society was held on Tuesday, November 30, 1909, at the Institution of Electrical Engineers in London. Mr. James Swinburne was elected president.

A paper by Dr. Henry J. H. Sand dealt with the **electro-analytical determination of lead** as peroxide.

This investigation was carried out with the object of elucidating the cause of the discrepancy between the statements of various experimenters regarding the behavior of an electrolytic lead peroxide deposit in drying at 200°. All authors agree that the peroxide deposit retains water at this temperature, but whereas Hollard and Bertriaux give an analytical factor of 0.853, most other investigators find a factor of approximately 0.864, the theoretical factor being 0.866. Incidentally, the effect of varying conditions on the coherence of the deposit was also studied.

It was found that at 200° a lead peroxide precipitate is capable of absorbing moisture from a damp atmosphere, and an increase of as much as 1.7 per cent of the weight of the deposit has thus been obtained. On heating in a dry atmosphere at the same and higher temperatures, the peroxide loses its water exceedingly slowly.

The most satisfactory results were obtained by depositing the peroxide in such a manner that it is practically free from water owing to electric endosmose on leaving the bath. The conditions are a high temperature and a large current density (with a rotating cathode). The deposit was dried by means of alcohol and ether in the identical manner employed for metal precipitates.

A paper by Mr. Arthur Jacquerod discusses the influence of dissolved **gases** on the **electrode potential** in the system of silver, silver acetate, aq.

Mr. Arthur Jaquerod also contributed a paper on **ionisation** in aqueous solutions in lead acetate and cadmium acetate.

A paper entitled "The **calorimetrical analysis of hydrated salts**" was communicated by Prof. F. G. Donnan and Dr. G. D. Hurst. The authors point out that the interpretation of the heats of solution of hydrated and partially dehydrated salt given by Thomsen in his Thermochemische Untersuchungen is in various cases either erroneous or unsatisfactory.

It is shown that Thomsen's data for sodium carbonate indicate," when correctly interpreted, the existence of only the

hydrates with 1, 7 and 10 mols. water per mol. anhydrous salt. The authors' experiments confirm this result.

In the case of copper sulphate, neither the experiments of Thomsen nor those of the authors indicate more than the existence of the hydrates $CuSO_4 . 5H_2O$ and $CuSO_4 . H_2O$, though the hydrate $CuSO_4 . 3H_2O$ is known to exist.

This calorimetric method may be employed as an aid in the discovery of the existence of salt hydrates, though it is probably neither so easy nor so reliable as other well-known methods.

The Aluminium Situation.

According to a communication published from trade circles in the *Frankfurter Zeitung* and noticed in the London *Electrical Review*, the hopes of an understanding among the French producers of aluminium, after months of preparatory work, had recently to be abandoned. The inland understanding between the French firms, who produce a very large part of the total output of aluminium, would naturally have formed the basis for a far-reaching combination. But from the beginning the allotment question or the regulation of the output of the individual works seems to have been incapable of solution.

It is quite obvious that the powerful undertakings which during the period of high prosperity carried out what were doubtless exaggerated extensions now object to renounce their comprehensive schemes in relation to production. Nevertheless, they will find themselves, if they also wish to improve the price of the metal, in the situation which they have themselves created through the excessive straining of the (late) syndicate prices.

The price of aluminium improved from the time of the appearance of the first syndicate rumor in June, 1908, but since the recent definite abandonment of this community of interests consumers have manifested a natural reserve. This circumstance is aggravated by the accumulating offers of intermediaries who seem, owing to the continued circulation of syndicate rumors, to have supplied themselves with large quantities at the lower prices prevailing until recently. But as their speculative purchases were not so quickly realized as they had hoped for, they are inundating the market with cheap prices, which again appear at about 1s. 3d. per kilogram (14 cents per lb.) and lower for crude aluminium.

Apart from this, consumers are deriving advantage from the situation. There is no doubt that the consumption of the metal is increasing and must in all probability continue to progress if the price is kept within normal limits. These may be regarded as from 1s. 5d. to 1s. 7½d. per kilogram (16 to 18 cents per lb.) for crude ingots or plates with an extra of from 5d. to 5½d. (10 to 11 cents) for the rolling out of sheets. On the basis of this charge for sheets, the manufacture of aluminium vessels and various articles is remunerative, but the overstepping of this maximum would reduce the consumption. In conclusion, it is stated that the present average price of 1s. 3d. per kilogram (14 cents per lb.) for crude aluminium only represents a small profit, but it no longer directly results in a loss.

All this refers, of course, to Europe. For this country the protective tariff is to be taken into account.

CORRESPONDENCE.

Electrical Smelting of Copper Ores.

To the Editor of Metallurgical and Chemical Engineering:

SIR—The electric furnace has acquired a footing in the iron and steel industry, but as yet little has been done in the field of copper smelting. As an accessory to a matte-smelting blast furnace or reverberatory, electric smelting is, however, capable of being employed to advantage in many cases.

As a general proposition, the fuel energy required to increase the temperature of one unit of mass by one unit of temperature increases greatly with the initial temperature of the mass, and to raise the temperature of a given mass from 1500 to 1600 deg. requires more fuel energy than is required to heat it from 100 to 1100 deg., and vastly more than is required to heat it from 500 to 600 deg. In general it increases in a geometrical progression as the temperature increases. Heat generated in a mass by electrical resistance is, on the other hand, cumulative, and except for loss by conduction and radiation it takes no more current and costs no more for 100 deg. increase of heat at 1500 deg. initial temperature than at 1000 or 500 deg.

This points to a field where electrical heat can be used to advantage, viz., for carrying the summit of the smelting load under conditions where fuel heat does the work of smelting up to the point where an electric current can act upon the material to generate internal heat, the electric current then finishing the operation. In other words, to an adjustment of conditions such that the smelting by fuel heat will proceed to the point where there will be formed a semi-fluid mass capable of flowing and forming a bath, when the completion of the smelting will be done by electric heat.

In the smelting of sulphide ores we are dealing with material of a complex nature, composed of elements or constituents having different temperatures of fusion, and the constituent of lowest smelting temperature fuses first and the others in the order of fusibility.

As in the freezing of molten alloys and mixtures where the element of highest freezing temperature solidifies first and the elements of lower freezing temperature remain as land-locked bodies within the chilled mass until the temperature falls to their respective freezing points, so in the fusion or smelting of ores containing components having different fusion temperatures, the constituents of lowest smelting temperature fuse first and drain down into the bath, carrying downward particles of unfused constituents of a higher fusion temperature or leaving a spongy mass composed of such constituents. In straight fuel smelting in a blast furnace conditions require that the fusion of all elements, those having a high-fusion temperature as well as those of a low smelting point, be accomplished at or above the plane of the tuyeres. Below that plane the space is filled with incandescent coke, which, being in a non-oxydizing atmosphere, remains as a support for the charge. At the plane of the tuyeres everything except the coke melts and drains down through the incandescent coke bed into the bath. The result is that in straight fuel smelting the consumption of coke is largely in excess of theoretical requirements, for it must be sufficient to make a free-flowing fluid of all material and preserve the coke foundation. In straight pyritic smelting the problem appears to be complicated by the small margin between the fuel energy of the contained sulphur and iron and the heat requirements of complete fusion, and further, probably, by the formation of strata of material of high fusion temperature below the tuyere plane in lieu of the incandescent coke foundation before noted.

The electrical heating of the bath in a matte smelter will permit of the cutting down of the coke charge to the point where the coke will do the smelting of the more fusible material and the electric current the balance, or if the fuel value of the contained sulphur and iron approximates to that required for the basic smelting, the use of coke can be dispensed with. This can be secured by a hearth of a trough character with electrode terminals, and also a fore hearth with a flowing tap, so as to maintain in the trough hearth a bath of constant level or cross-section. The hearth should so discharge into the forehearth that there will not be an accumulation of matte. The current, of course, is of large amperage and low voltage, the resistance of copper slag indicating a working voltage of from 5 to 7 volts. Estimates indicate that 1 electric horsepower will give a control of 200 deg. (Fahr.) per minute per ton of ore capacity per day, so that 1 electric horsepower will heat 1.4 pounds matte-slag 200 deg. per minute.

This should suffice, for it is to be borne in mind that the elec-

[illegible] is cumulative, and is added to material already close to the fusion point; that the time or capacity element is the one to be affected by the quality of the current; that if the volume of current is small it simply takes a longer time for it to supply the deficiency for smelting a given quantity of semi-fluid material than it will take when the volume of current is larger. In other words, that the electric current is a governor supplying just what heat is needed for each unit of product to give a uniform temperature.

With the coke charge reduced to the amount simply required for the basic fusion and all consumed at or above the tuyeres, or in the case of pyritic ores eliminated entirely, the result will be that the space below the tuyere plane will be occupied by material of an open, spongy character of progressively varying fusibility with that of highest fusibility at the bottom. The fused products of the fuel smelting draining down into the bath will, with the excess of heat they carry down, complete the smelting of matter of the lowest smelting temperature met with.

Elements of lowest fusibility will be smelted out in advance of elements of higher fusibility, and consequently the material resting on the bath and pressed down into the bath and extending up to the plane of the tuyeres will be of varying fusibility with that of highest fusibility at the bottom. The electric heat is therefore expended directly on the material of highest fusibility, while fuel smelting starts with the material of lowest fusibility and works up in the scale of temperatures, so to speak, to the elements of higher fusibility. Under proper adjustment of current and fuel, fuel smelting and electric smelting will meet at the point where, everything considered, the result is most economical.

If accessory electric smelting is to be used as a control for pyritic smelting so as to make it practical, the current need not necessarily be so very heavy, for, being cumulative, the electric heat will in time supply the balance required.

Naturally, we look to hydro-electric power, where it is obtainable, as the source of current supply. But accessory electric smelting will probably permit of the use in many cases of comparatively cheap fuels, oil, producer gas, waste, heat, etc., in lieu of high-priced coke.

Electric smelting can not only be employed in connection with blast-furnace smelting, but it can be used in reverberatories. The adaptation to reverberatory practice of electric smelting as above outlined calls for a new type of reverberatory, one in which there can be maintained two long banks of ore or charge with a trough between, this trough having electrode pockets or connections at both ends and a forehearth with a flowing tap. The reverberatory has rows of charging holes in the roof next to the sidewalls and the charge, banked against the sidewalls and protecting them, presents a crest of summits and saddles with slopes leading down to the central trough into which the semi-fused material drains.

In a reverberatory furnace a large amount of waste heat is available for current generation, and thus the entire heat energy can be utilized, either primarily as fuel heat or secondarily as electric heat.

STORY B. LADD.

Washington, D. C.

Electric Smelting of Iron Ores at Domnarfvet and at Nykroppa, Sweden.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—In order to show to what extent the Iron & Steel Associations of Sweden are putting faith and confidence in the work and results already accomplished in electric smelting of iron ores by the use of the "Elektrometall" Company's electric smelting furnaces, it is interesting to learn that the "Jernkontoret" at a meeting in November last, appropriated the sum of [illegible] kronor toward the immediate construction of an experimental electric furnace plant at Trollhättan, of the above type and of [illegible] daily capacity.*

As already has been mentioned in the *Electrochemical and Metallurgical Industry*, a 700-hp electric furnace of this type was in successful operation at Domnarfvet for some time, and, according to the very complete report† of Lars Yngström in the transactions of the "Jernkontoret" (Part 9, 1909), these results have demonstrated that the question of electric production of iron from ore "is now economically as well as practically solved."

The furnace which the Swedish Iron & Steel Association is to erect, therefore, ought not to be considered as a further experiment in this direction, but as an "experimental plant" to which any iron manufacturer or mine owner can send his ore and have the same treated for obtaining information as to its suitability for such a process, the purpose for which the resulting metal would be best adapted, and the cost of manufacture, as compared with iron produced from the same by means of charcoal or coke.

The business arrangements arrived at between "Jernkontoret" and the "Elektrometall" are reported in the Swedish daily press to comprise the following principal parts:

The "Elektrometall" shall without further cost execute and furnish all necessary detailed drawings and specifications of building and furnace appliances; also during the construction period furnish all required advice and information.

The "Jernkontoret" shall defray all expenses in connection with the construction of the plant and have full charge and final decision as regards the same. The Jernkontoret reserves the right of exercising the patent rights for their own use or to dispose of such rights to others, in consideration of a first payment equal to 2 krone per electric horse-power for each particular size furnace or furnace type erected, besides a royalty of 1.25 krone per metric ton pig iron produced according to the "Elektrometall" Company's patents during the life of the same.

From this, however, is excepted the present experimental plant, for which no further charge or royalty shall be paid.

As regards power for the present plant, the "Jernkontoret" has made an arrangement with the Swedish "Hydro-Power Commission" whereby during two years they will, for this particular purpose, obtain up to 3000 hp at Trollhättan for the annual sum of 10,000 krone (equal to about $3) per horse-power year.

In the petition to the Government the "Jernkontoret" gives some interesting information on the results obtained from the late electric smelting experiments at Domnarfvet and Nykroppa that during said experiments charges of different kinds of iron ores and briquettes have been used (both high and low in P-contents); that the coal consumption has been brought down to about one-third of that of the ordinary blast furnace practice; that the maximum efficiency of the furnace so far has been only 58 per cent (whereas that of the ordinary blast furnace can be considered to be about 80 per cent), but that there is good reason to expect a still further reduction in heat losses for the furnace proposed, by changes in the water coolers about the electrodes and in adopting thicker furnace walls. Mention is also made of the superior quality of some of the electric pig iron made from the Tuolluvara ore at Nykroppa and used in one of their 10-ton O H furnaces. This was white iron, which usually is cold and sluggish, but which here proved to be the very reverse, the iron being hot and liquid, and allowing even a higher percentage of ore charge than the ordinary. The cold drawn pipes made from the steel products proved also to be of superior quality.

Owing to the successful results obtained from the Swedish experiments a large Norweg an electric smelting plant has also been decided on, to be constructed in accordance with the principles embodied in the "Elektrometall" Company's patents.

E. A. SJOSTEDT.

Conservation and the Chemical Engineer.*

BY SAM. P. SADTLER.

We have heard much in the last year or two concerning the Conservation of our Natural Resources and we shall, I feel certain, hear much more in the next few years, as the facts elicited from the preliminary studies of the subject come to be understood by the public at large. The importance of the subject will grow correspondingly as the matter is studied by the thoughtful citizen and his appreciation of it will in time be reflected in the activity of the statesmen at Washington in the proposing of remedial measures.

Conservation let us note, however, represents the third stage in the history of the development of Natural Resources.

The first stage is Exploration or discovery. This is the era of the prospector and has given us in this country some famous episodes. We need only recall the discovery of gold in California in 1849 and the way in which it operated to attract adventurous spirits from the older parts of our country, or the repetition of the same story with the discovery of the rich gold deposits on the Yukon and at Nome in Alaska.

The first discovery of rich petroleum deposits of Western Pennsylvania in the early sixties brought, similarly, multitudes of prospectors or "wildcatters," as they came to be known locally, and this experience has been repeated also from time to time as great petroleum gushers or powerful gas wells have been reported in various sections of the country, resulting in the opening of new fields, as in Ohio, Indiana, Kansas, Texas and Oklahoma.

The second stage is Exploitation, when these lavish gifts of nature are worked with a view mainly of increasing production and usually in a wasteful way with no thought of the exhaustion of the supply.

As illustrations of this stage we need only cite the way in which our coal mines have been worked. In Bulletin 394 of the U. S. Geological Survey (Papers on the Conservation of Mineral Resources) we find the statement that "it has been estimated that the actual loss or waste sustained through coal left in the mines in conducting mining operations amounts to 50 per cent of the quantity produced and marketed." Worse than this, when the Anthracite Coal Waste Commission made its report in 1893 they estimated that "for every ton produced 1½ tons were lost."

One of our most valuable gifts of nature is the natural gas, which is associated more or less directly with petroleum. It is a fuel of the greatest value, being nearly pure hydrocarbon in its composition. Yet we find in the same Bulletin of the Geological Survey before referred to the following: "As to the amount of natural gas which is being wasted daily, no accurate statistics have been attempted and the judgment of Dr. I. C. White, State Geologist of West Virginia, may well be accepted to the effect that no less than 1,000,000,000 cubic feet of gas are wasted every twenty-four hours. Of this, undoubtedly the larger part is wasted in the production of oil." This waste, Dr. Day of the Geological Survey says, "practically equals the annual consumption of natural gas reported for 1907. This waste should furnish light for half the urban population of the United States."

The exploitation of our once great timber resources and the resulting denudation of great tracts of land and the evils to the soil which have followed in the train of this ruthless waste have been so graphically portrayed by the U. S. Forestry Bureau and others recently that I need not more than allude to this case of reckless extravagance.

It is not my intention, however, to take up this evening the question of the conservation of our natural resources and the absolute need thereof, as so ably developed in recent reports of the "National Conservation Commission," the Forestry Bureau, and other official publications, nor yet the part played by the chemist in this Conservation of Natural Resources which has been so ably reviewed by Dr. Bogert in his recent Presidential address before the American Chemical Society.

What I would like to do is to indicate that these same three stages of exploration or discovery, exploitation or effort at production, and finally conservation, are to be seen in the history of every great chemical industry and to point out, that, while it is the part of the chemical engineer to aid in the exploitation step, what is still more important is his part in counselling and indicating how the wholesome influence of conservation can be applied, so as to broaden and extend the scope of the industry, to maintain and add to its remunerative character and to give it stability and promise of permanence.

Let us illustrate this view by examples and take first the great petroleum industry to which reference has already been made in speaking of the era of exploration when the petroleum fields were first outlined by the work of the prospector and driller. The second stage of exploitation began to draw upon the help of those who were chemical engineers in fact if not by title. The development of the distilling and refining processes came first. Starting with the old cheese-box still with its circle of heating grates under it, there was a change, following upon the discovery of the "cracking process" as applied to crude oil, to the present form of cylindrical still with its movable cover to regulate the chilling of the vapors during the latter part of the operation. This simple feature in distilling enables the refiners to get 75 per cent or more of burning oil from the crude petroleum instead of the 45 per cent of a normal fractional distillation, while producing a residuum which can be advantageously distilled for paraffin oils.

The proper control of the acid and alkali treatment of the crude distillates, the change from the old forms of presses for paraffin scale to the modern filter press, the introduction of bone-black filtration for reduced oils and residuums all contributed to develop and expand enormously the several parts of the industry to which they were applied. With these improvements in large scale methods went the inauguration of improved testing and analytical methods, so that uniformity of product so essential for sound business development was secured.

Let us turn now to the newer evidence of the work of the chemical engineer in the way of conservation as illustrated in this same industry. The collection and utilization for fuel purposes of the uncondensed gas from the distillation of crude oil is one of the important economies that has been generally adopted. The working up of the sludge-acid and recovery of not only sulphuric acid but of valuable side products is now a feature of the larger refineries. The introduction of clay filtration to improve the quality of the heavier grades of oils is an important advance as well as a step of economy. The production of gas oils from the less valuable crude oils has also become an important industry as these are of great value for gas-making and gas-enriching. The more thorough utilization of residues is also a feature of recent years. From these residues are now made excellent road oils for the aid of the good roads movement. The petroleum pitch is all utilized also partly for electric light carbons and partly for fuel purposes. Most promising of all, however, is the result, not as yet fully attained, but most certain of solution in the immediate future, viz., the utilization of crude petroleum of the lesser valuable kinds and residuums in internal combustion engines for the development of power.

A second typical industry is that of coal distillation. We have already spoken of the wastage in the mining of coal. It is not necessary here to speak of the corresponding waste in its utilization as fuel. We will speak solely of the distillation of coal. This treatment may be carried out from either one of two points of view, and the exploitation in each case has been pushed with great energy, utilizing all available chemical and engineering skill. The first is the distillation for the manufacture of illuminating gas. While the mechanical side of this process has advanced steadily, particularly after the introduction of regenerative firing and mechanical stoking, the chemical side did not

*Presidential address delivered at the second annual meeting of the American Institute of Chemical Engineers in Philadelphia, Dec. 8, 1909.

advance so rapidly. While the coal-tar is no longer thrown away, unless it be in very isolated localities, the proper chemical utilization of this tar has lagged behind both in this country and in England. On the other hand, the true conservation of this valuable side-product and the development of its possibilities has advanced in a notable degree in Germany, the home of the coal-tar industry. Here the research chemist and the chemical engineer have gone hand in hand in the building up of a great industry or rather two industries based upon the utilization of the coal-tar, the manufacture of the coal-tar dye colors, and the manufacture of synthetic medical preparations possessing valuable therapeutic characteristics. Besides these most important and highly developed illustrations of conservation, we have, however, some minor utilizations of coal-tar or products from the same that deserve mention. Thus the manufacture of creosote oils for the preservative treatment of wood, the roofing-pitch and tar-paper manufacture and the use of pitch in the briquetting of coal are illustrations of value given to the coal-tar and its products.

The thorough extraction of the ammonia and the impurities like the cyanides from the ammonical liquor and the production of commercially valuable products from them is, moreover, an accomplishment in the way of conservation. The utilization, too, of the gas carbon for the manufacture of electrode carbons, battery plates and for electric light carbons is another illustration of this work.

The second method of distilling coal is that for the production of coke for metallurgical purposes. This has been developed or more properly exploited to such a degree that, according to the "Mineral Resources of the United States," published by the U. S. Geological Survey, the production of coke for the year 1907 was 40,779,564 tons, of which, however, 35,171,665 tons were produced in beehive ovens. In these, as is well known, only the fixed carbon of the bituminous coal is saved and all volatile constituents including gas, tar and ammonia are absolutely wasted. On the other hand, 5,607,899 tons of coke were produced in by-product recovery ovens and the value of the by-products (gas, tar and ammonia) obtained therefrom amounted to $7,548,71. It is easy to reckon from this what the loss was on the 35,171,665 tons of coke made in beehive ovens. In fact, the article on "Coal," in Bulletin 394 before referred to, says with reference to this, "at the prices which prevailed in 1907, the value of the by-products wasted in beehive coke-ovens was a little over $53,000,000."

But the result achieved by the chemical engineer in the working of this by-product over represents more than merely saving certain by-products. The gas produced can be separated by the perfect control of the method into "poor gas" for fuel purposes and "rich gas" for illuminating purposes so that the highest economy or conservation of values is thereby attained.

Another industry in which the chemical engineer has worked first for the purpose of exploitation and later for conservation of material and values is the starch industry. Starch, as we all know, is one of the most widely distributed vegetable products and has always played a great part in the world's supply of food. In Europe, it is potato and wheat starch, in the United States it is corn starch, and in tropical countries it is rice, tapioca, sago, etc., that are the important varieties of this cereal food. Not only has the production of starch been developed, however, for food purposes, but enormous quantities of the starchy substances serve as the starting point in the fermentation industries. Then we have the use of both starch and its alteration product dextrine in the textile industries and the production of glucose as the product of the hydrolysis of starch, and the manufacture of nitro-starch and its utilization in the explosive industry. All of these industries have attained a high degree of perfection by the application to them of a chemical understanding of the nature of starch and its alteration products and the devising of processes by which the several reaction changes could be carried out with exactness and economy. What that means as applied to one single branch of the starch industry, those of us who had the opportunity on the occasion of our meeting last June to go through the works of the Corn Products Company at Edgewater, N. J., can appreciate. The glucose production of the United States in 1907 is stated to have been 830,000 tons, requiring 40,000,000 bushels of corn as raw material. But besides the production of the solid grape-sugar and the liquid glucose for a great variety of uses, the separation of the germ of the corn from the starchy portion has made possible the production on a large scale of corn-oil, a product adapted for a wide range of uses—from soap making to the manufacture of rubber substitute.

Turning now to Inorganic Chemistry for an illustration, we have a splendid example of the work of the chemical engineer in the direction of conservation in the case of the natural and artificial nitrate industry, to which latter the Germans have already given the expressive name of "air-salpeter." The great source of nitrate for forty or more years past has been the deposits on the west coast of South America furnishing the so-called Chili salpeter or sodium nitrate. This has been drawn upon increasingly until in 1908 the quantity shipped was 1,730,000 tons, valued at $87,500,000. But the Chilean deposits are far from being inexhaustible. It is estimated that if the annual consumption increases merely by 50,000 tons, and this is to be reasonably expected, from 30 to 40 years will see the practical exhaustion of this supply. So in 1899, Sir Wm. Crookes startled the industrial world by calling attention, in what the newspaper men would call a "scare-article," to the nitrogen problem and the necessity of maintaining a supply of nitrogenous plant food if the world's food requirements were to be met. Crookes pointed out the way of relief when he said "the fixation of atmospheric nitrogen is one of the greatest discoveries awaiting the ingenuity of chemists. It is certainly deeply important in its practical bearings on the future welfare and happiness of the civilized races of mankind." The chemical engineer has responded nobly to this demand for conservation of available nitrogenous material by the working out of practical methods for the manufacture of what we called "air-salpeter." It must not be supposed, however, that success was easily obtained.

Not only were the usual experimental difficulties to be overcome but, as Prof. Bernthsen has well shown in his address before the London International Congress of Applied Chemistry in May last, there are theoretical difficulties of the most serious kind standing in the road of ready fixation of atmospheric nitrogen and oxygen in the form of nitrogen oxides convertible into nitrates. So it happened that the first large enterprise of this kind, the process of the Atmospheric Products Company, established at Niagara Falls, had to be given up as commercially unavailable. This was followed by the Birkeland and Eyde process, started in Norway with the cheapest water power to be found, and this is still in successful operation. A few years later (in 1905) the Schönherr process was worked out by the Badische Anilin and Soda Fabrik, also using Norwegian water power and still later the Pauling process at Gelsenkirchen, near Innsbruck, in Tyrol. The Schönherr process seems to be the most successful.

It produces a 40 per cent nitric acid, calcium nitrate, or calcium or sodium nitrite, according as the absorption part of the process is modified. All of the processes mentioned require the cheapest electrical energy which can only be developed by cheap water power, and thus far best developed in Norway. Prof. Bernthsen states, however, that probably within a few years the annual output of calcium nitrate or "air-salpeter" will reach 100,000 tons. As this involves first the fixation of atmospheric nitrogen, and second the use of "white coal," as water power is sometimes fancifully called, it is a true lesson in conservation of natural resources, especially as it also enables us to replace a rapidly disappearing natural product.

Closely related to this recently developed inorganic industry of air-salpeter is the slightly older one of calcium carbide and

its offshoot the cyanamide or "nitrolime" industry. With the production of calcium carbide in the electric furnace in 1892 by Willson and the publication of Moissan's work on the electric furnace in 1894, sprang into existence a great industry, as the acetylene gas lighting made possible thereby had great advantages. Isolated lighting plants, acetylene lamps for automobiles and carriages, luminous buoys and signals, a new material for lampblack manufacture and other utilizations all were rapidly developed. The perfecting of the furnaces and the process for this manufacture of carbide enlisted the attention of electrical and chemical engineers and at the present time the world's production of calcium carbide is estimated to be about 200,000 metric tons per annum, largely in countries like Norway, Italy and Switzerland where cheap water power is available, as well as in the United States at Niagara Falls and Sault St. Marie. This production, however, for the time being outran the demand for carbide for acetylene lighting.

Relief from over-production by finding new outlets and utilizations is always to be preferred to closing of works already in operation, so chemical engineers have found new possibilities for calcium carbide. By far the most important of these is the production from calcium carbide of calcium cyanamide by the action of nitrogen gas, as worked out by Drs. Frank and Caro. We have here an exothermic reaction in which nitrogen is absorbed by the carbide with the production of calcium cyanamide and carbon. This takes place at a temperature of from 800° to 1000° C., much below that needed for the carbide manufacture. Not only can all the nitrogen of this cyanamide be converted into ammonia by decomposition with steam, but it is gradually decomposed by the chemical and bacteriological constituents of the soil into ammonia, which becomes fixed by the vegetable mould and is so held. The cyanamide is also convertible into calcium cyanide by melting with fluxes, into dicyandiamide for dye-color manufacture, into urea, guanidine and other hitherto relatively expensive organic compounds. The dicyandiamide is already used as a "deterrent" in smokeless powder manufacture, reducing the temperature of the explosion without diminishing explosive force, and the crude calcium cyanamide with certain fluxes under the name of "ferrodur" is employed for case-hardening of iron and steel.

The statement is made that the works for the manufacture of "nitrolime" now in operation or in course of construction have a capacity of 166,000 tons per year.

The illustrations of conservation, whether from the point of view of better utilization of materials, or the production of new and varied products or the recovery of what were waste products, could be greatly extended did time allow.

We might refer to the way in which sulphur recovery has been worked out in the alkali industry, or to the manganese recovery in connection with the chlorine production from manganese dioxide, so that "recovered manganese" is to-day a most valuable article of commerce. Or we might note the saving resulting from the manufacture of reclaimed rubber, but these and similar illustrations of the conservation theme as influenced by the work of the chemical engineer will have to be passed by for the present.

That there are numerous problems as yet unsolved of equal and possibly greater importance than some of these discussed will also be conceded by those possessing even a moderate acquaintance with chemical industries.

One of these problems, for instance, is the recovery of the valuable constituents of the waste liquor of the sulphite wood-pulp process. A German authority states that every liter of this waste liquor contains 120 gms. of organic material as against 10 to 15 gms. of mineral substance. Dr. A. Frank estimated that in 1904 there was wasted in this way in Germany 300 million kilograms of organic material, concerning which we know that it has value in several directions. In this country, the sulphite wood pulp process has also an extensive development and the same waste liquor is run off into our streams.

A somewhat different problem, but one of even greater importance, is the loss of valuable metals in smelter smoke and fumes. The American production of bismuth is not over 10,000 lbs. a year and considerable amounts of bismuth and bismuth compounds are imported every year. Yet it is estimated in the forthcoming report of the U. S. Geological Survey for 1908 that 880 lbs. of bismuth per day are being thrown off in the smoke of the great Washoe smelter at Anaconda, Mont., and with this also go copper, lead, zinc, arsenic and other mineral products. One way of saving much of this lost material is pointed out in noting that the replacing of smelting methods by electrolytic methods, possible in some cases, allows these metals to be recovered from the deposited slimes.

In conclusion let us emphasize the fact that our chemical industries need not merely development or exploitation, but if they are to continue to flourish as we are drawn more and more into international competition they must have the newest and best results of chemical research applied by the experienced chemical engineer. New and better materials must be sought, better processes evolved, economies effected at all possible stages, and waste products carefully looked after. The most successful chemical industries in the world, which show the highest scientific and technical development and which are steadily expanding and throwing out branches, are those of the great German chemical companies. Organizations like the Badische Anilin and Soda Fabrik, which have by their employment of both research chemists and chemical engineers effected industrial revolutions, one after the other, like the introduction of artificial indigo, the contact sulphuric-acid manufacture, and last of all the production of air-salpeter or artificial nitric acid and nitrates, are those which reap the rich commercial rewards and for the reason that they have done the work and earned them. The hope of a successful American Chemical Industry lies in the same direction.

The Electric Shaft Furnace at Domnarfvet, Sweden.

A full and interesting account of the experiments made with the electric shaft furnace at Domnarfvet, Sweden (see our Vol. VII, p. 419), and the conclusions drawn therefrom has been contributed by Mr. LARS YNGSTRÖM to the *Jern-Kontorets Annaler*, No. 9, 1909, from which the following abstract has been made.

The author first makes a heat analysis of the smelting process and determines the amount of coal and electric energy necessary to make a given grade of pig iron, which is assumed to have the following composition: Three per cent C, 1 Si, 96 Fe, and traces of Mn, P, S, Cu.

Further, it is assumed that the ore consists of Fe_3O_4 with 60 per cent iron plus burnt lime, and that the escaping gases contain 30 per cent CO_2 and have a temperature of 200° C.

In making the computations, the following heat values are assumed:

To reduce 1 kg Fe from Fe_3O_4 requires 1650 cal.
" 1 " Fe " Fe_2O_3 " 1800 "
" 1 " Si " SiO_2 " 7830 "

To oxidize 1 kg C to CO_2 generates 8080 cal.
" 1 " C to CO " 2470 "

1 kw-hour corresponds to 857 cal.

The smelting and overheating of 1 kg of pig iron requires 280 cal.

1 kg. of slag[1] requires 595 cal.

Specific heat for dry furnace gas, 0.245 cal. per kilograms.

It is also assumed that all raw material introduced into the furnace has an initial temperature of 0° C., that the ore is free of water and CO_2, and that the lime is burnt.

[1] This figure may appear somewhat high, but it was thought advisable to increase it by about 100 cal. over the value obtained by experiment in the laboratory; partly on account of the high temperature of the slag and partly on account of the formation of carbide in the slag when electricity is used.

Amount of C required per 1000 kg of pig iron.

Reaction formulas:

(a) $13\ Fe_3O_4 + 40\ C = 12\ CO_2 + 28\ CO + 39\ Fe$.

(b) $13\ SiO_2 + 20\ C = 6\ CO_2 + 14\ CO + 13\ Si$.

According to formula (a) 960 kg of Fe are obtained from 1325.71 kg Fe_3O_4 and requires for reduction 210.99 kg. C, forming 576.70 kg of gas ($CO_2 + CO$).

According to formula (b) 10 kg Si is obtained from 21.43 kg SiO_2, and requires for reduction 6.59 kg C., forming 18.02 kg of gas ($CO_2 + CO$).

The total amount of carbon required is:

For the reduction of 960 kg Fe	210.99 kg
For the reduction of 10 kg Si	6.59 "
For carbon in the pig iron	30.00 "
Total chemically pure carbon	247.58 kg

Amount of Slag.

With a mixture of ore and lime containing 60 per cent Fe there is required 1600 kg of this mixture for 960 kg Fe. This corresponds to 1325.71 kg Fe_3O_4.

Corresponding amount of slag	274.29 kg
SiO_2	21.43 "
Amount of slag per ton of pig iron	252.86 kg

Amount of Gas.

According to form. (a) there is developed $CO_2 + CO$ . . 576.70 kg

According to form. (b) there is developed $CO_2 + CO$ . . 18.02 kg

Total per ton of pig iron . . . . . 594.72 kg

Calorific Value of Fuel.

When 1 kg C combines with O, forming a gas which contains 30 per cent CO_2 by volume, there is generated $0.3 \times 8080 + 0.7 \times 2470 = 4153$ kg-cal.

Heat Balances.

Heat required:

Reduction of 960 kg Fe from Fe_3O_4 at 1650 cal. . . .	1,584,000 cal.
Reduction of 10 kg Si from SiO_2 at 7830 cal. . . .	78,300 "
Melting and overheating of 1000 kg of pig iron at 280 cal.	280,000 "
Melting and overheating of 252.86 kg of slag at 595 cal.	150,452 "
Heating of 594.72 kg $CO_2 + CO$ to 200° C. at 200×0.245 cal	29,142 "
Total	2,121,894 cal.

Heat developed:

Combustion of 217.58 kg C at 4153 cal.	903,610 cal.
Heat developed by electric current	1,218,284 "
Total	2,121,894 cal.

Therefore, the theoretical amount of electric energy required is

$$\frac{1,218,284}{857} = 1420 \text{ kw-hours.}$$

The curves in Figs. 1 and 2 are based upon calculations similar to the foregoing. The amount of carbon in coke and charcoal being assumed as follows:

Coke { C = 85 per cent; H_2O = 5 " "; Ash = 10 " "

Charcoal { C = 85 per cent; H_2O = 12 " "; Ash = 3 " "

Fig. 1 applies to iron reduced from Fe_3O_4, while Fig. 2 applies to that reduced from Fe_2O_3.

The experiments at Domnarfvet began in the spring of 1907, and with but few interruptions have continued up to the present time. The electrical equipment installed especially for these tests consists of a 3000-volt, 60-cycle, 900-hp synchronous motor direct connected to a three-phase 25-cycle generator which supplies energy to a transformer set up near the furnace. The generator permits of an adjustment of e.m.f. in small steps from 300 to 1200 volts. This wide range of voltage has made it possible to test furnaces under various conditions and of various designs with the most favorable voltage. The fields of the synchronous motor and generator are excited by a 20-kw, 220-volt, direct-current generator mounted on the same shaft. The set is started by a 500-volt, three-phase induction motor also mounted on the same shaft. The machines are all equipped with instruments which permit the calculation of the energy and power being used.

From the switchboard the electric energy is carried by copper bars laid in conduits under the floor direct to the three-phase air blast transformers. These transformers have a combined capacity of 1500 kilovolt-amperes with a transformation ratio of 14 to 1—that is, by means of voltage control at the generator, the secondary voltage of the transformer can be changed in small steps from 20 volts to 80 volts.

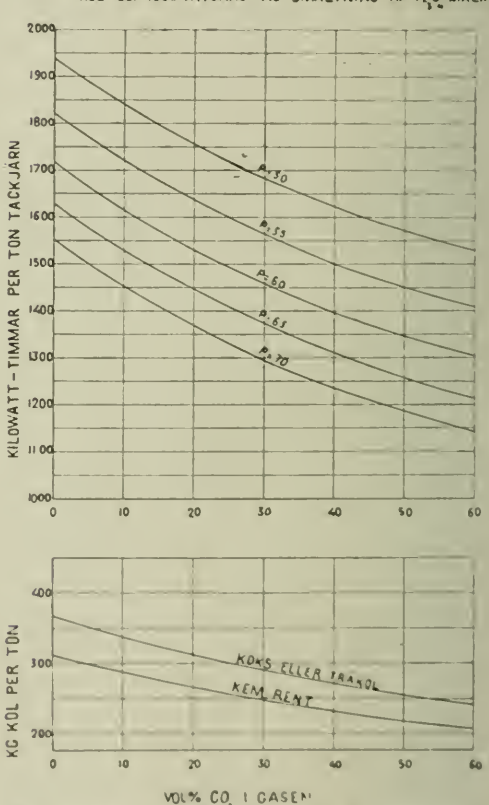

FIG. 1.—ENERGY AND CARBON REQUIRED FOR SMELTING IRON FROM Fe_2O_3.

(The abscissas in both diagrams are per cents. by volume of CO_2. The ordinates of the upper diagram are kilowatt hours per ton of pig iron. The five curves refer to 50, 55, 60, 65, 70% Fe in the ore. The ordinates in the lower diagram are kg. per ton. The upper curve refers to coke or charcoal, the lower to chemically pure carbon.)

For controlling the operation of the furnace an instrument board is mounted nearby which contains one three-phase precision wattmeter for unbalanced phases; three ammeters, one for each phase, and one voltmeter with switch for connecting to various phases.

The ammeter and wattmeter are connected through series transformers to the leads. The voltmeter and wattmeter potential coil are direct connected to the leads. Right under the instruments are placed the hand wheels for controlling the position of the electrodes in the furnace.

The first experiments were performed with an electric furnace constructed in accordance with certain patents owned by Messrs. Grönwall, Lindblad and Stalhane, who together formed a company Elektrometall in Ludvika. These gentlemen, together with the Grangesbergs Company, were also interested in the continued experiments.

The construction of the first furnace is shown in Fig. 3. It

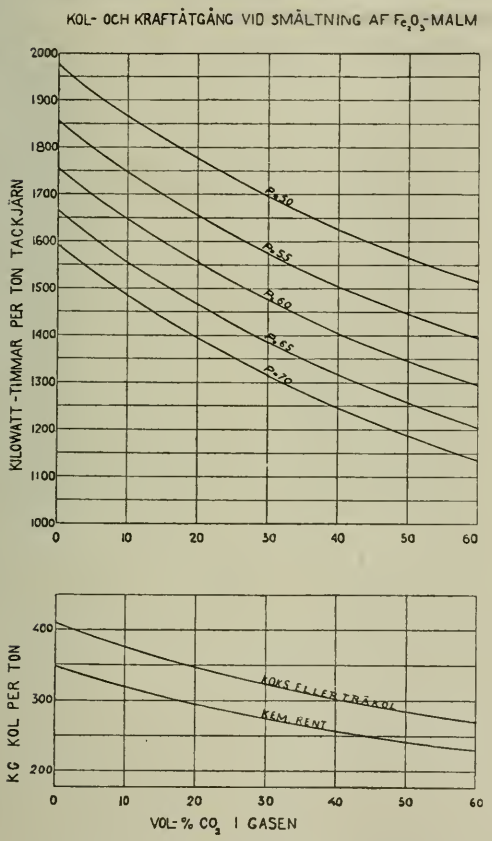

FIG. 2.—ENERGY AND CARBON REQUIRED FOR SMELTING IRON FROM Fe_2O_3.

(The abscissas in both diagrams are per cents. by volume of CO_2. The ordinates of the upper diagram are kilowatt hours per ton of pig iron. The five curves refer to 50, 55, 60, 65, 70% Fe in the ore. The ordinates in the lower diagram are kg per ton. The upper curve refers to coke or charcoal, the lower to chemically pure carbon.)

is a shaft furnace with the hearth of tamped quartz. In the bottom of the hearth there are large grooves. The one in the middle leads to the tap hole, while the other two on the sides lead to wells which are filled with iron. The bottoms of these wells are made of copper plates covered with pressed graphite blocks, each of these forming the electrodes of the furnace.

The furnace is started with blast as in the ordinary shaft furnace, and when a sufficient amount of iron has collected in the hearth, the blast is turned off and the electric energy turned on. It was intended that the electric current entering the furnace through the iron on the one side, passing through the furnace on the other side would, partly by the overheating of the molten iron and partly by the energy lost by the resistance in the path, liberate enough heat to melt the ore.

For short periods of time this furnace could operate, but it was found impossible to obtain a hearth bottom which could stand the high temperatures. Therefore, this furnace was rebuilt in the form shown in Fig. 4. The same principle is used

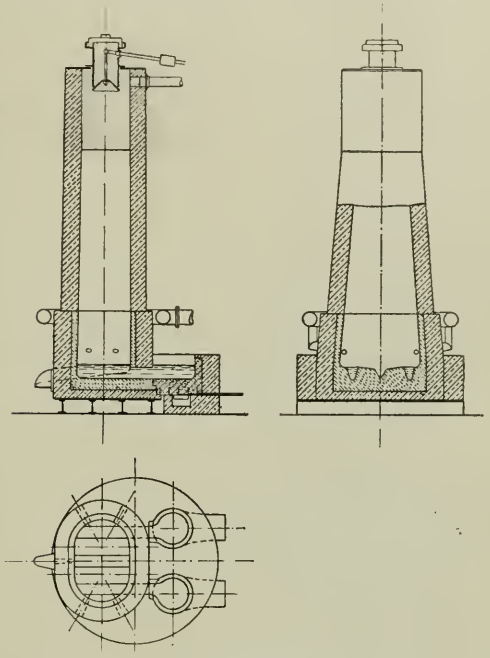

FIG. 3.—FIRST DESIGN OF ELECTRIC SHAFT FURNACE. (TWO BOTTOM ELECTRODES.)

as in the first furnace, but the lower part is more solidly constructed. The electric energy enters and leaves at opposite sides of the furnace. The most important changes consisted in using magnesite. This material gave very much better results than were obtained in the first furnace. However, it had the disadvantage of being a relatively good conductor of electricity at very high temperature.

These first experiments clearly indicated that the solution of the problem could not be accomplished with furnaces where the current was introduced into the molten iron at the bottom of the hearth. Therefore, the next furnace was built along different lines.

The first one of this type, shown in Fig. 5, was a small shaft furnace with one graphite electrode in the bottom, and two diagonally opposite electrodes in the walls of the furnace at a certain height above the bottom. During the experiments the upper electrodes became considerably burnt and had to be exchanged for ordinary adjustable carbon electrodes fitted with water-cooled jackets The connections were so made that the current could be conducted either across the shaft from one electrode to the opposite one, or through the bottom electrode. This furnace proved much more durable than the former ones, but had the disadvantage that the walls of the shaft were badly damaged around the electrodes, due to the very large amounts of energy there liberated.

If it could be so arranged that the electrodes were surrounded by ore, the heat which in this furnace was lost in heating up the walls, could be turned to good account, and the walls made

to last a great deal longer. In accordance with these ideas a furnace was constructed as shown in Fig. 6, and experiments with this one showed that the problem was very near its successful solution and led to the construction of the large shaft furnace which forms the subject of this article. The construction of this furnace is shown in Fig. 7, which in appearance is very similar to an ordinary blast furnace in which the tuyeres

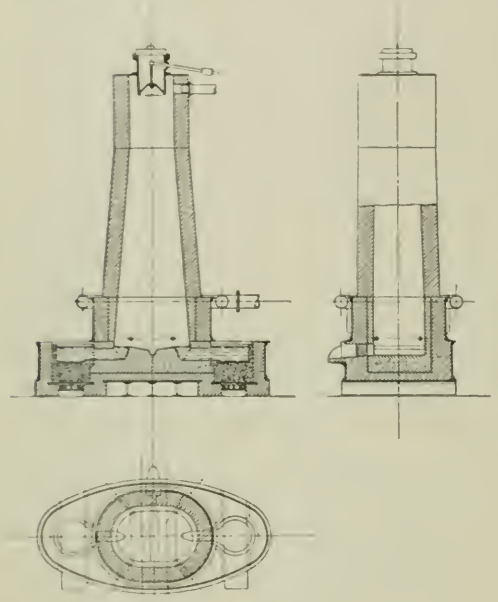

FIG. 4.—SECOND DESIGN OF ELECTRIC SHAFT FURNACE. (TWO BOTTOM ELECTRODES.)

are replaced by electrodes. This furnace was described by Dr Eugene Haanel in a paper before the Electrochemical Society, May 6, 1909 (this journal, Vol. VII, p. 251, June, 1909).

The melting chamber is in the form of a crucible about 2,250 mm in diameter and 1500 mm high and lined with magnesite. As the charge descends through the opening in the top of the melting chamber, free space is left between the charge and the upper walls. This point is of great importance and has much to do with the success of this type of furnace. Experiments have shown that the angle assumed by the descending charge is about 50° or 55° with the vertical.

This free space around the roof of the chamber is utilized for cooling the walls and electrodes by drawing comparatively cool gas from the tunnel head and forcing it through tuyeres into the space at the top of the crucible, as shown in the illustration. This method of cooling is extremely efficient, since the heat absorbed by the gases is given off to the charge as the gases ascend to the top of the shaft, and, therefore, no heat is lost except by radiation from the tuyeres. By this method of circulation, of gas a better distribution of heat throughout the charge is obtained than is usual with other types of electric furnaces.

The electrodes are introduced through the roof of the melting chamber passing through the free space into the charge, which is made up of two square carbons 33 cm on a side, having a total cross-section of 2178 sq. cm. The electrode holder consists of a strong steel frame which supports wedges by means of which the copper plates conducting the electricity from the cables are pressed against the faces of the electrode. The position of the electrodes is controlled by the steel cable which passes by means of pulleys to a winch situated at the instrument board opposite the furnace. The external part of the electrodes is protected with an armored asbestos covering to prevent oxidation in the air, and the stuffing boxes are water-cooled, special devices, not shown in the illustration, being provided to prevent the gas within the melting chamber from leaking out around the electrodes.

The shaft, which is 5.2 meters high and 1.525 meters internal diameter at the largest section, rests upon an iron framework supported by six cast-iron columns. This construction permits repairs to be made on the melting chamber without in any way disturbing the shaft itself.

This furnace was put into operation the seventh of last May, and with the exception of a few slight interruptions was run continuously to last July, and could have continued for an indefinite period had it not been necessary for other reasons to shut it down.

The furnace is started as an ordinary blast furnace with the electrodes removed, then several charges of charcoal and coke are put in, the electrodes are inserted and the shaft filled with ore and lime, together with charcoal and coke. The amount of charcoal used is reduced continually and at the end of the first week the charges consist of 100 kg ore, 3 kg lime (burnt),

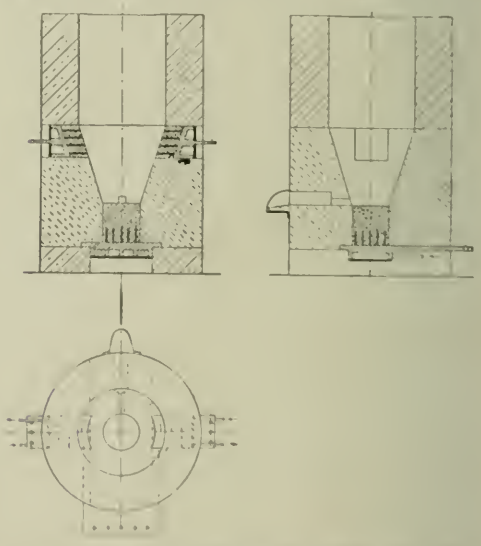

FIG. 5.—THIRD DESIGN OF ELECTRIC SHAFT FURNACE. (ONE BOTTOM ELECTRODE AND TWO ELECTRODES IN WALLS.)

24 kg coke, and from that time on 100 kg of ore, 4 kg of lime and from 22 to 24 kg coke. The greatest number of charges per day when operating with coke was 62. The shaft held 72 charges, and, therefore, the number of times it was filled per day was 0.86.

When operating with charcoal the number of charges per day was 80, and since the shaft then held only 41, the number of times the shaft was filled per day was 1.95. When using charcoal alone the amount of carbon per 100 kg of ore varied from 21 to 28 kg. The charcoal was measured by volume, 1 hektoliter being taken as 16 kg, because of its relatively high moisture content.

At the beginning, when the furnace was still cold in the bottom, the current existed principally under the arch. The path of the current followed close under the arch, and, therefore, the latter was considerably heated and its surface partially melted. As soon as the gas circulation was put into operation

its cooling effect was very effective, the temperature of the arch sunk and the heat descended toward the bottom of the crucible. As the lower part became heated, the resistance was lowered, and, therefore, the current gradually worked down toward the bottom of the furnace. After the furnace was in normal operation, the gas circulation could be discontinued for several days without any tendency for the current to rise toward the roof of the crucible. Charcoal in the charge seems to assist in holding the heat near the bottom.

In several cases it happened that the quantities of iron produced did not correspond to the percentage in the ore. For example, in one week from 48 tons of ore only 17 tons of iron, which corresponds to 27 tons of ore, was obtained; while in the following week from 22.6 tons of ore, 23 tons of iron were obtained. This can be explained only by the fact that more or less of the reducing iron clung to the walls and bottom of the furnace in the first case, and was drawn off in the second.

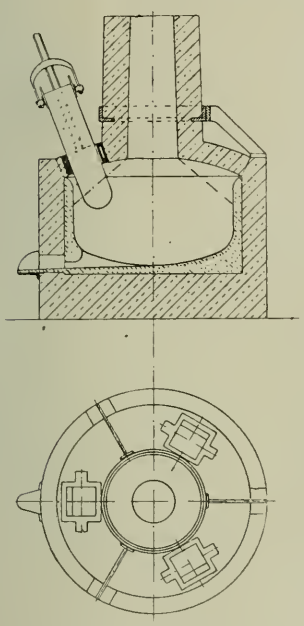

FIG. 6.—ELECTRIC SHAFT FURNACE. (THREE ELECTRODES IN WALLS.)

The furnace was sometimes cold on account of there being too much carbon in the charge. However, this was quickly overcome by increasing the amount of ore. Moreover, such an occurrence can be easily prevented by proper construction of the furnace walls. The slag indicates plainly an excess of carbon in the charge, in which case calcium carbide is formed and an odor of acetylene gas is noticeable.

In certain cases the furnace showed a tendency to hang, but after the amount of charge along the walls had reached 80 per cent of the total this difficulty disappeared. Experiments proved that an electric furnace can be charged with ore dust if all the dust is introduced along the walls and the height of the charging head is so chosen that the upper surface comes somewhat under the gas-collecting cylinders so that the dust cannot be drawn over into the gas tuyeres. The briquetting of ore dust is, however, not necessary with electric furnaces.

A few slight mishaps during the operation of the furnace had a certain influence on the results obtained. For example, near the end of the first week the water jacket of one of the electrodes sprang a leak so that it was necessary to operate the furnace for a time with only two electrodes. Again, on account of failure of one of the electrical machines, the transformer at two different times was connected directly to the high-tension line and operated at 60 cycles instead of 25.

While in operation no surges of current or sudden peaks were noted. Even when tapping the furnace the measuring instruments indicated no fluctuation, and, therefore, the electrodes required very little attention, being regulated about once a day, and in one case they ran five consecutive days without any adjustment. The largest current carried by the electrodes was about 9000 amp per phase. The power factor at 25 cycles was from 0.8 and 0.9, while at 60 cycles it was about 0.7.

The amount of energy which can be delivered to the furnace depends largely upon the internal resistance of the mass; the larger the resistance, the greater the amount of energy which can be developed without increasing the current to excessive values. With 25 cycles, 80 volts was sufficient to produce the proper current, and with 60 cycles, 65 volts was necessary. The voltage impressed upon the furnace depends principally upon the fuel used and its relation to the ore. Table 1 shows this relation.

TABLE 1.

Charge—	Volts across electrodes	Current per electrode in amperes
Coke in excess	34	9,600
" not in excess	36	8,800
Charcoal in deficiency	60	6,300
" right	54	7,600
" in excess	48	7,600
Coke and charcoal in excess	35	9,200
" " " right	48	7,600

In operation the furnace proved to be very steady and easy to care for, and it was tapped about every six hours.

Seven different kinds of charges were used in the tests. Since the principal purpose of the experiments was to develop

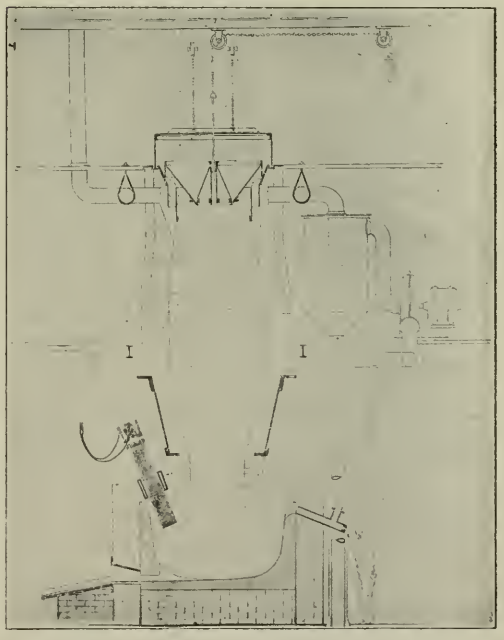

FIG. 7.—FINAL DESIGN OF ELECTRIC SHAFT FURNACE.

a practical furnace construction, the charge at first consisted of a rich, easily reduced hematite ore which had a considerable phosphorus content. As a result, however, later on it was impossible to produce a first-class pig iron from first-class ore, because the iron was always adulterated by phosphorus from the ore which remained on the walls of the furnace.

Burnt Lime.		Coke.		Charcoal.	
Fe_2O_3	0.5%	C	85%	C	65-80%
MgO	2.0%	H_2O	4%	H_2O	12-20%
CaO	96.5%	O + N	1%	Ash	3%
Al_2O_3	0.2%	Ash	10%		
SiO_2	0.2%	(0.5-0.7% S)			

The composition of charge mixtures was as follows:

Mixture No. 1.

826 charges of
100 kg Grängesbergs Skarnings ore
4-5 kg lime (burnt).
10-26 kg coke.
10-0 charcoal.

Mixture No. 2.

575 charges of
10 kg of Langgrufve ore (briquettes)
11-18 kg of lime (burnt).
0-21 kg of coke.
20-0 kg of charcoal.

upon the amount of this carbon which is oxidized to CO_2. In short, the amount of carbon used under normal conditions is always the same as would be theoretically required. The results of experiments demonstrate the truth of this statement. The carbon required can be expressed mathematically in terms of the CO_2 in the furnace gases. If M denotes volume per cent CO_2 in the gases, and k the percentage of carbon in iron, the carbon required in kilograms per metric ton of pig iron, if iron occurs in Fe_2O_3, is:

$$C = \frac{321.43\,(100 - k)}{100 + M} + 10\,k.$$

If Fe occurs in Fe_3O_4, we have

$$C = \frac{285.7\,(100 - k)}{100 + M} + 10\,k.$$

2-5 kg Lime (burnt)
16 kg charcoal

[illegible] air and enter the furnace, providing it is well built and properly run, the amount of fuel for different ores depends entirely upon the amount of carbon in the fuel and also

These formulas hold for chemically pure carbon and gas which is made up exclusively of CO_2 and CO.

It is evident that the circulation of the furnace gases has a definite influence on the amount of CO_2 in the gases. The experiments showed that the CO_2 content increases with the gas circulation, and that the temperature of the gases is very considerably increased. For instance, when operating with mixture No. 3, the CO_2 content of the gas was increased from 14.5 with no gas circulation to 39 per cent with constant circulation, and the corresponding temperatures were 75 deg. C. in the first case and 220 in the second. The experiments also indicated the existence of a certain circulation velocity which was best in each particular case, and that an increase over this velocity increased the temperature of the gases accompanied by a decrease in CO_2 content which was quickly noticeable.

What velocity to use in each case must be determined by experiment, and will depend to a certain extent upon the volume of the shaft. No exact measurement was made of the flow of gas used in these tests, but it may be estimated as about four or five times the rate at which the gases were generated in the furnace.

The high hydrogen content of the gas is noteworthy. This is partially due to the hydrogen in the charcoal, but to a greater extent to the moisture in the fuel, because when the moist gases are blown into the lower part of the furnace where the temperature is very high, hydrogen is developed.

A question which assumes great importance when judging the economical results which can be obtained with electric furnaces is that of the life of electrodes. With mixtures Nos. 1, 2 and 7 the consumption of the electrodes, on account of certain disadvantageous conditions, was abnormal; therefore, in the results given in Table 3 these tests have been omitted.

The electrodes were of Swedish make, and consisted of retort carbon with a permissible current density of 4 amp per sq cm. The experiments indicate that the figures for the burning of the carbon can be reduced by about 30 per cent by using a higher quality of electrode.

Still more certain is the fact that the electrode consumption can be greatly reduced by suitable design. For instance, the electrodes used in the experiments were only about half consumed when they had to be discarded on account of their insufficient length. Therefore, if some construction be devised which would permit the continuous feeding of the electrode a great saving would be accomplished.

Of great importance is the electrical efficiency of the furnace. By electrical efficiency is understood the ratio between the electrical energy used and the amount of energy required to reduce the ore. The electric current in the furnace produces the following effects: (1) It raises the mass to the proper temperature. (2) Melting and overheating of pig iron and slab. (3) Driving off of H_2O and CO_2. (4) Heating of the gases. The sum of these quantities of energy, less the heat which is developed by reduction of carbon by oxygen in the ore, to a gas of greater or less CO_2 content, is just the amount of energy which theoretically must be supplied from the electric circuit, and which is denoted as the theoretical electric energy. The losses of electric energy are as follows: (1) Heat in the cooling water around the electrodes. (2) Heat in leads and contacts. (3) Radiation from the walls of the furnace.

In tabulating the results obtained with the various mixtures, Nos. 1, 2 and 7 have been omitted, because during the first two runs the furnace was not yet in normal operating condition, while the last run was too short to give consistent and reliable results.

TABLE 3.

Mixture No.	Electrode burning. Kg. per ton	Electrode consumption. (metric) pig iron.
3	1.4	11.1
4	7.0	12.7
5	8.1	14.3
6	6.9	19.4
3—6	5.2	13.8

The losses varied between 230 and 270 kw, and were higher near the end of the experiments than in the beginning. These losses may be divided approximately as follows:

Cooling water	118 to 125 kw
Loads in contacts	40 kw
Radiation	110 to 180 kw
Total losses	239 to 275 kw

By building furnaces of higher capacity, for instance of 2500 hp, and by paying particular attention to the factors which have a bearing on the heat losses, it is not impossible that a furnace can be built with an electric efficiency of about 80 per cent—that is, one which surely could produce more than three metric tons of pig iron every per horsepower year, provided a rather rich ore is used.

It is difficult to estimate from the experiments which have been made what the maintenance cost of a furnace would be. The present furnace, however, has been in continuous operation for 85 days, and successfully met all requirements which indicate a durable furnace.

The furnace's weakest point is the arched roof of the crucible, but by cooling with circulating gas this can be prevented from burning out. The bottom of the crucible and the walls of the shaft did not show any appreciable ill effects from the heat more than the ordinary shaft furnace. It has happened that the masonry back of the electrodes became red hot, but by suitable cooling devices, utilizing circulating gas, this can easily be overcome. Moreover, if the masonry should burn out at these points, it is easy to repair them without interfering with the operation of the furnace. Therefore, by suitable design and proper material in the walls, the durability of the furnace can be rendered thoroughly satisfactory.

With electric furnaces it appears that the process of producing iron of different compositions is under more exact control than in other processes, since it consists mostly in regulation of voltage, which will produce corresponding changes in temperature. It has been possible to produce iron with less than 1 per cent carbon, but in this case the slag content had a noticeable amount of iron. As a rule, the carbon content varied between 2 and 3 per cent.

With an electric furnace it is very easy to increase the silicon content in the pig iron. Analysis has shown 3.61 silicon, but it is also possible to reduce the silicon content as low as from 0.3 to 0.5 per cent.

It can be counted on that all the phosphorus in the charge will enter into the composition of the iron, but it should be noted here that in electric furnaces only one-third as much fuel is used as in the ordinary shaft furnace, and that in the production of first-class charcoal pig iron it is the charcoal which supplies the phosphorus. Therefore pig iron produced in an electric furnace will have a lower phosphorus content than that produced in an ordinary blast furnace.

A special advantage of the electric furnace is the possibility of driving off sulphur. Using a mixture of about 5 per cent sulphur, an iron with less than 0.005 per cent sulphur was produced. The requirements for driving off of sulphur are as in electric steel furnaces, a basic slag and a high temperature. The calcium carbide formed by electric current also plays an important part in the driving off of the sulphur.

Judging from the tests made at Domnarfvet, it appears that the production of iron from iron ore in electric furnaces is successfully accomplished, both technically and economically speaking, but in order to obtain a more complete knowledge of the subject, these experiments should be continued on a larger scale. If electric operation is to be worth while, however, sufficient electrical energy at low price must be available. Summing up the advantages of the electric shaft furnace over the ordinary blast furnace, they are as follows:

1. Lower installation cost, since blowing engines and heating apparatus are not required.
2. Saving of about two-thirds of the fuel required in an ordinary blast furnace.
3. Ore dust can be used without briquetting.
4. The generated gases have a high heat value when free from nitrogen.
5. The possibility of producing in the furnace itself low-carbon iron.
6. Less attendance, since the transportation and charging of two-thirds of the fuel used in ordinary shaft furnace is done away with.

Evidently it would be advantageous to combine electric shaft furnace for iron ore reduction with an electric steel furnace, which would refine the melted iron from the electric shaft furnace.

We are obliged to Mr. Yngström for a copy of his paper from which this translation was prepared, and to the editor of *Jern-Kontorets Annaler* for placing the cuts of the illustrations at our disposal.

Rapid Method for the Determination of Chromium in Chrome and Chrome-Nickel Steel.

BY N. M. RANDALL.

Dissolve one gm. steel in 25 cc nitro-sulphuric acid. When in solution remove from the heat and add about 15 or 20 cc cold water. Rotate the liquid in the beaker and drop in at once about one gm. sodium bismuthate and continue to whirl for a few seconds.

Replace on the light and boil hard, the permanganate formed

by the sodium bismuthate is rapidly decomposed and there remains a clear violet liquid (manganic metaphosphate) which on further boiling converts the remainder of the chromium to CrO_3.

Decompose excess of manganic metaphosphate with 1/2 cc or more if necesary of dilute HCl; boil one minute, cool somewhat, dilute to 200 cc with cold water, add slight excess ferrous ammonium sulphate, and titrate with permanganate.

The end reaction is very sharp and leaves no doubt in the operator's mind.

The results are accurate and an analysis can be completed in 10 minutes.

This method has not yet been tested in presence of W and Mo.

Acid for dissolving steel:

300 cc nitric acid, 1.42 sp. gr.
300 cc sulphuric acid, 1 pt. acid, 3 pts water.
300 cc water.
100 cc phosphoric acid, 85 per cent
1½ grams manganese sulphate.

Sparrows Point, Md.

Uniformity of Blast Furnace Operation.

By Jos. W. Richards.

One of the great essentials for the attainment of high efficiency of furnace operation is the careful striving of the engineer for uniformity of working conditions. In practice it is the irregularities which fetch the superintendent out of bed at midnight, keep him on duty 24 or 48 hours at a stretch, and unduly sprinkle his hair with silver. What engineer has not experienced the sense of restful satisfaction which comes from seeing a furnace at last operating regularly, and has not felt at the same moment the conviction that his entire future problem was the preserving of those conditions by uniformity in everything pertaining to the furnace and its operation?

The history of blast furnace practice, when intelligently understood and properly appreciated, is mostly a record of efforts to attain greater uniformity of operation. The directions which these efforts have taken are in regard to the quantity, dryness and temperature of the blast; the composition, size of lump and relative proportions of the fuel, flux and ore; the times of charging, and the distribution of these within the furnace; the running out of pig iron and slag; the quality and temperature of iron and slag; the preserving constant of the interior shape of the furnace. We will discuss each of these in detail.

Composition of ore, flux and fuel.—No furnace can run successfully or uniformly unless the materials charged are of nearly uniform composition, both individually as ore, flux and fuel, and collectively as charge. To this end managers prefer to have large stocks of supply of uniform materials. An iron ore mine which yields millions of tons of ore a year of nearly uniform quality is of great relative value to the blast furnace plant which can be economically connected. Our Lake Superior ores are just such from the huge Alabama deposits are inferior and numberless rich ore "Minette" of Luxemburg is inferior and have yet all these are rightly valuable deposits because of their uniformity and reliable uniformity. To find more deposits of uniform composition is to seek as for a jewel of great price.

Similar considerations govern the supply of flux and fuel. Large quantities of materials of uniform quality, an abundant supply of coke of constant composition are worth the best efforts of the metallurgist and are comfort to the manager even when procured.

Taking the above conditions, when several varieties of ores, fluxes or fuels in varying proportions have to be worked, the foremost desirable for the greatest and successful working upon the chemical laboratory. Each variety of ore must be analyzed and the several varieties thus stored in certain proportions to obtain a uniform ore mixture. It is safe to say in general terms that this is not any laboratory necessary preliminary to large deposits of uniform material are few and far between.

Given satisfactory and uniform quality of materials brought to the plant, or proper ore mixture, flux mixture or mixed fuel at hand, they should be preserved from rain and snow in order that they enter the furnace substantially dry. The charging one day of dry materials and the next of wet materials soaked by heavy rain will necessarily cause irregularities in the furnace working; use the charges either dry, moist or wet, but whichever it may be, uniformly so, and another cause of irregularity is scotched.

Size of Lump.—All of us have wondered, on first looking at the charges being dropped into a blast furnace, how the furnace could digest them in such huge lumps. And the query is a reasonable one, the blast furnace has a foot, belly and throat, but it has no teeth or anything corresponding to masticating apparatus, and it only too frequently suffers from indigestion. We should help it by "Fletcherizing" the charges. The old-fashioned manager who says it does not make any difference, and throws in lumps of ore, flux and fuel as large as a football, simply does not know that uniformity of lump, in fairly moderate size, is a great advantage to the furnace. One furnace in the United States, upon the advent of a new manager with the above idea in his head, increased its output 25 per cent, accompanied by much greater regularity of working, by merely sizing the ore, flux and fuel down to that uniform lump size for each which by experimenting was found to give the best efficiency.

Composition of the Charge.—Given fixed or uniform qualities of ore, flux and fuel, the proportioning of these so as to have the proper relations between them is in the hands of the chemist. He knows the analysis of each constituent, and calculates the charge upon the two requirements of (1) a given composition of slag to be produced and (2) a given quantity of inert material or burden (ore plus flux), melted down per unit of fuel used. The most important factor in the regularity of furnace working is the one under consideration. If this is faultily or improperly attended to, nothing can save the furnace from working with continued irregularity.

In making these calculations the chemist relies primarily on the accuracy of his analyses and upon experience as to what is required. By experience we mean that he must know from numerous tabulations of analyses of proper slags, within what limits of composition he must bring his slag in order to have it work properly; from similar tabulations he must know the maximum quantity of ore plus flux which unit weight of his fuel can properly take care of in the furnace. He thus draws on his experience, or the recorded and reliable experience of others, as the working basis or assumptions on which to base his calculations. All this must be accurately and reliably worked out; if not, uniformity of furnace working is impossible from the start.

Intervals of Charging.—Three meals a day is a good regime for others, but the blast furnace would soon be "dead" on it. Most furnaces are charged at intervals of five minutes to half an hour, neither of these is the ideal of proper feeding. Uniform driving requires uniform charging. Intermittent charging causes a varying height of charge column, a varying back pressure of blast in the furnace, a varying temperature of the issuing gases, and discontinuously varying layers of material descending the furnace shaft. The ideal charging method is undoubtedly continuous charging, without interruption. This will insure continuity in place of the above mechanical irregularities. It has not yet been adopted for any blast furnace, as far as the writer is aware, but the constant feed of mechanical stokers, and particularly of certain modern gas producers, has certainly laid the foundation for the solution of this problem. The ideally regular working furnace of the future must necessarily have constant and continuous charging. Modern furnaces are approximating this by reducing to the smallest possible time the intervals between charges.

Distribution of the Charges.—An enormous amount of thought and effort has been given to the subject of securing uniformity in this respect. The bell top and mechanical distrib-

utors have done much to overcome the difficulties and to substitute mechanical regularity for human fallibility and carelessness. Every blast furnace manager will admit that the devices so far employed are not yet perfect; there is large room for their improvement. Coke will gravitate towards the middle and ore towards the sides, or *vice versa*, with attendant irregularity in the descent of the charges and working of the furnace. The mechanical engineer can here greatly help the metallurgist to solve a difficult and an important problem affecting uniformity of furnace operation.

Running Out of Iron and Slag.—Present practice is essentially discontinuous in this respect, with consequent irregularity in the working of the furnace. Pig iron is tapped two, three or four times a day, slag is usually tapped every one or two hours. It was formerly the practice to shut off the blast while tapping, but the irregularity caused by this was so great that it has been successfully abandoned. A few furnaces run off slag continuously. This solves half the problem, or advances half-way towards ideal regularity.

The continuous running out of slag and matte is a *fait accompli* in copper and lead blast furnaces, and has really been a most important improvement over discontinuous tapping, with the consequent irregularity of working of the furnace. Attempts to apply these principles to the iron blast furnace have succeeded so far only with regard to the slag. It is highly desirable, from the standpoint of uniform working, that both iron and slag should flow continuously from the furnace; whether through siphon taps or large settlers, etc., is a matter of detail. If this were accomplished, the sudden rushes of hundreds of tons of molten material can be dispensed with, casting machines of limited size could take care of the pig iron, small ladles handle the slag, and, best of all, the conditions in the crucible of the furnace, as far as concerns the presence of melted slag and iron, be kept perfectly uniform.

Interior Shape of the Furnace.—In the "days of old" this was a cause of secular irregularity which often resulted in the "blowing out" of the furnace. It has been nearly completely overcome by improving the lines of the furnace, making the walls thin, and using water cooling. Such long-period irregularity, however, is rather different from the short-time variations which we have been considering.

Temperature of the Blast.—When blast furnaces were blown by cold air the variations in its *temperature* as it entered the furnace from, say, 0° C. to 40° C. (32° Fahr. to 100° Fahr.), made little difference to the running of the fuurnace; it certainly made much less difference than the difference in the quantity pumped by the engines, resulting from the difference in temperature of the outside air. But that is another consideration, and we can say of the temperature of the blast, considering its *temperature only*, that a difference of 40° C. would not make more than 40° C. difference in the furnace temperature, and therefore introduce a rather small irregularity. When hot blast was first used, the iron pipe stoves, operating continuously, furnished blast of fairly constant temperature, with unimportant variations. When, however, regenerative fire-brick stoves came into use, it was soon evident that the discontinuous principle of operation caused great variations in the temperature of the blast, which would be highly heated when first turned onto a hot stove, and have its temperature fall several hundred degrees by the time the stove was turned off blast. This difficulty was met by increasing the number of stoves from two to three, four, and even five, and thus correspondingly reducing the time that any one stove received blast. The uniformity of high blast temperature thus attained has been satisfactory, but not entirely so. "Equalizers" were next invented, to stand near the furnace to receive the hot blast from the stoves and to smooth down the "peaks" and raise the "valleys" in its temperature. They are gigantic thermal flywheels. Fine results have been thus achieved, and splendid uniformity of blast temperature has correspondingly increased the uniformity of the furnace working.

Moisture of the Blast.—Nature varies the atmospheric conditions so that one day the air may be very dry and the next very moist; close observation shows large variations at times even from hour to hour. But increase in moisture cools off the furnace and renders the working irregular. The manager could meet these conditions by varying the amount of fuel in the charge, if he knew 24 hours in advance how much moisture he had to prepare for, since it takes about that time for a fresh charge to descend to the foot of the furnace. That being impossible, he tries to meet the unfavorable conditions by increasing the temperature of the blast. That keeps him "on the jump"; it is meeting one irregularity by practising another, and is never more than moderately successful.

Mr. Gayley first practically solved this problem by drying the blast, reducing its moisture at all times to a small, substantially uniform amount. He achieved success, and his improvement is notable in two ways, viz., it reduces the absolute amount of moisture, thus effecting material saving in fuel, and it leaves it uniform in amount, thus abolishing one of the most annoying and serious causes of furnace irregularity. To have the moisture *uniform* is a great advantage; to have it *uniformly low* is the splendid combination which works the wonders which Mr. Gayley has achieved.

Quality of the Blast.—Everyone skilled in blast-furnace art knows that the more air is pumped into a furnace the faster it runs. Shut the air off, and it stops working altogether. Regularity of working, at uniform rate, is therefore absolutely dependent upon the furnace receiving a uniform weight of oxygen per minute.

This depends absolutely on two factors, the speed of the blowing engine and the temperature of the air entering its cylinders. Make these uniform, and uniform rate of running of the furnace results.

Mr. Gayley has attacked this problem also. In his United States patent 935,628, of September 28, 1909, he describes appliances for furnishing the blowing engine with air of substantially uniform temperature. Where the engine is distant from his drying apparatus (which also cools the air) he passes it to the engine through pipes or conduits with heat insulating sides, protecting it from outside sources of variation of temperature. so that the temperature furnished to the engine shall be constant.

Mr. Gayley avers that he is the discoverer of the great importance of the substantially uniform temperature of the air as it enters the blowing engine. It is now in order for some one to "discover" that it is of equally great importance for the *speed* of said blowing engine to be kept substantially uniform—of which equally important fact there is no hint or mention, suggestion or suspicion in the aforesaid patent, specification or claims.

It seems to the writer that variations in the temperature of the air as it comes to the blowing engine will always be present, that absolute uniformity in this respect cannot be practically attained, and that a much more practical solution would be the following: Construct a mechanical thermo regulator controlled by a thermometer, which will increase the speed of the engine 1 per cent for every 3° C. rise in temperature of the incoming air (1 per cent for every 5° Fahr. rise), and the problem of supplying the furnace with a constant weight of air is solved with exactness.

The Preparation of Silicon in the Laboratory.

BY SAMUEL A. TUCKER.

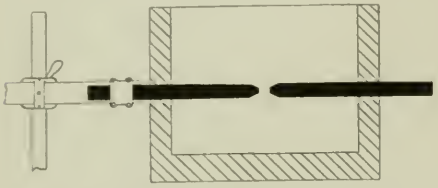
The reduction of silica by carbon in the electric furnace is now carried on quite extensively on a large scale, but its preparation in the laboratory has presented certain difficulties. The method here described can be worked very successfully and affords an interesting application of the electric furnace.

For the charge 12 kilos of a mixture of sea sand and gas coke in the proportion of 77 parts of sand to 25 of coke are used, and placed in a rectangular furnace of firebrick giving a working space of about 10 in. x 9 in., by 8 in. high, which

should be cemented as tight as possible to prevent the admission of air. At a height of 3 in. from the bottom at each end openings are provided for the two horizontal graphite electrodes, 2 in. diameter. These electrodes are adjustable so that at the start the two ends are in contact, but as the operation proceeds they can be separated about 1½ in. to 2 in.

Alternating current was used in the experiments here described and the capacity available was about 50 kw, with means for regulation of the voltage and an impedance coil to balance the arc at the start. After a minute or so the impedance coil was cut out of the circuit and the arc maintained at the terminals of the alternator.

The charge being well mixed and ground so as to pass, say, a 10-mesh screen, is placed in the furnace to a depth of 3½ in. The arc can then be started by withdrawing the electrodes and more of the charge added, carefully at first so as not to ex-



LABORATORY FURNACE FOR PRODUCTION OF SILICON.

tinguish the arc, and then the rest of it so that the furnace is completely filled. The electrodes can then be given a little separation so that a longer arc is obtained and the process carried on in this way to the end of the run.

The first run was as follows:

Time, Min.	Amperes	Volts.
Start— 3	300	54
13	400	65
28	580	30
38	650	31
46	500	36
53	500	48
63	500	48
64	500	54
71	360	58
81	300	..

The gases find a vent and come off at considerable pressure and produce a great deal of vapor, so that good ventilation of the room in which these experiments are conducted is advisable.

After the furnace has cooled down it will be found that a crater has formed about the arc and that approximately one-quarter of the charge has been used up. The silicon is found on the bottom and in the above run the yield was 200 grams, having all the characteristics of the commercial metallic silicon. The next run was made with the same furnace and charge, but the energy was greater, as the following figures show:

Time, Min.	Amperes	Volts
Start— 1	220	57
15	550	30
60	590	54
63	660	55
68	670	58
70	680	61
74	660	69
79	700	69
80	740	71
81	760	72

The yield in this run was 400 grams, but the heat was somewhat too great for the size of the furnace, as the brick work was melted at places and ran down with the silicon at one the specimen obtained was not quite so clear as in the first case. For the size of furnace used about 20 kw-hours would be about right.

Boiler Feed Waters with Special Reference to Treatment.

By E. G Bashore.

Water, whether it falls to earth as rain or snow, is never pure. Rain water contains dissolved or absorbed gases—carbon dioxide (CO_2), oxygen (O), ammonia (NH_3) and during thunder showers, nitric acid. Precipitated moisture either in the form of ground water or surface water accomplishes a marked errosive action on the earth's crust, both through mechanical weathering and chemical action. The result of the former type is shown by matter in suspension, while the latter manifests itself through the dissolved impurities, and usually both processes occur simultaneously and mutually aid each other. By means of seeping water, easily soluble rocks, salts and minerals are dissolved as rock salt ($NaCl$), potassium chloride (KCl), magnesium chloride ($MgCl_2$), potassium carbonate (K_2CO_3), sodium sulphate (Na_2SO_4), potassium sulphate (K_2SO_4), sodium carbonate (Na_2CO_3) and gypsum ($CaSO_4$).

Many rocks and minerals which are sparingly soluble in pure water are put into solution in large quantities through the action of water containing carbonic acid (CO_2). Prominent in this class are the carbonates, calcite ($CaCO_3$), dolomite ($CaMg(CO_3)2$), magnesite ($MgCO_3$) and spathic iron ore ($FeCO_3$). Silicous rocks, such as hornblende (containing silica hydrate, with aluminium oxide, magnesium oxide, calcium oxide, soda, and usually some iron) may be decomposed by water containing carbon dioxide and certain component parts held in solution as bicarbonates of potassium, sodium, calcium, magnesium, etc. Furthermore, water may be contaminated with free acid. Such pollution may be due to organic vegetable acids from swamps or bogs, acid discharge from industrial plants or often drainage from coal or ore mines, sulphuric acid being prevalent where the ores are sulphides.

The importance then that the nature of a boiler-feed water bears to boiler operation may be made obvious by considering the quantity of water evaporated with its consequent residual products. For instance, in a 100-hp boiler using water containing only 7 grains of solids per gallon, over 300 lb. will be the quantity of solid matter for one month, while many spring waters would give over 2000 lb of residual matter, which must either be blown out or deposited.

As a result of the impurities that a feed water may carry, the following conditions are conventionally recognized in boiler practice, namely, scale formation, corrosion, foaming and priming.

Many reagents have been suggested for the treatment of feed waters, prominent among which are lime, soda ash, caustic soda, barium hydrate, barium chloride, tri sodium phosphate, petroleum, tannate of soda and tannin extract. Oak, hemlock, sumach, logwood, etc., are used for scale on account of tannic acid being extracted; also vinegar, fruits, molasses, distillery refuse, etc., have been used for the prevention or removal of scale, their action depending upon the presence or formation of acetic acid. Organic decoctions of the type are to be avoided, for often they are injurious to the iron and cause corrosion and pitting. No absolute rule can be established for the treatment of all feed waters, nor can a "cure all" be improvised, as each feed water from a different source will demand a treatment peculiar to itself.

The functions of the chemical treatment of a boiler feed water is to minimize the existing evil. However it must be remembered that every chemical reaction calls for a by-product, and while possible, through chemical treatment to

correct one unfavorable condition, it is also possible to induce another. But with intelligent operation, and through cognizance of the principles involved, a great saving in coal and labor in cleaning the boiler can often be accomplished in industrial plants through the application of a properly advised treatment.

The processes for conducting the treatment can be outlined under three heads:

(1) The addition of some substance in the water in the boiler;

(2) Preliminary treatment with heat in some special apparatus;

(3) Preliminary chemical treatment.

In considering the first subhead (1), emphasis should be made of the fact that a feed water should always be purified before it enters the boiler, for the pertinent function of a boiler is to generate steam and not to serve as a still in which to conduct chemical reactions. However, cases arise where it might seem advisable to use some "solvent" in the boiler for the purpose of converting the scale into a form in which it will be easily dislodged. Such "solvents" (usually soda ash, sodium hydroxide or tri-sodium phosphate) should be used with a thorough understanding of their reactions. Too great concentration should be guarded against on account of priming; the danger of severe foaming if animal or vegetable oil is present in the water on account of saponification should be borne in mind; and great care should be exercised that the dislodged scale does not cause overhauling and burning of the steel through accumulation.

Under the subhead (1) also comes the use of metallic zinc in the boiler. With waters which have a corrosive tendency on account of the presence of magnesium chloride, it has been found that metallic zinc suspended in the boiler counteracts the corrosive action. Where corrosion of iron is suspected through the agency of electrolysis, zinc is also a specific counteractant. With the use of zinc it is to be noted that the metal should be suspended at a point away from the direct heat of the furnace, and the utmost care should be taken that the zinc has perfect contact with the shell of the boiler. The use of such substances as clay, fats, starchy matters, wood extracts, vinegar, etc., in the boiler is certainly not to be recommended, and is to be avoided.

Under the second category feed-water heaters are properly classified. Aside from the economy gained by the boiler generating more steam through the use of flue gases or exhaust steam, which otherwise would go to waste, an important point is the reduction of the temporary hardness of the water. This is brought about through the liberation of the carbon dioxide at 212° Fahr., which holds the bicarbonates of calcium and magnesium in solution.

Many types of feed-water heaters are on the market, but it is hardly within the compass of this paper to describe them. However, for their successful operation it is necessary that sufficient exhaust steam be used to keep the temperature of the water to 212° Fahr if possible, and they furthermore must be kept clean.

When there is oil present in the condensed water a separator or filter should always be used.

The third sub-division, namely, purification by preliminary chemical treatment, leads to the process which will be given most consideration, for, as previously pointed out, the boiler is not a proper apparatus in which to correct the deleterious effect of bad feed water. This method is usually termed "the water softening process" and is conducted with the use of reagents in settling tanks. The simplest form of apparatus would be two tanks, one from which the treated and settled water would be drawn off for use, while the addition of reagents, agitation and settling would be going on in the other tank.

A number of reagents can be used to accomplish the precipitation of the scale-forming constitutents, but on account of the efficiency under most conditions and low cost, the lime, soda ash treatment will be considered. This process is conducted in settling tanks and is either intermittent or continuous. In the intermittent process fixed quantities of water are treated in the tanks with weighed amounts of each reagent required for the softening, while in the continuous system the requisite quantity of chemicals are introduced in direct proportion to the flow of the water. In order to insure the highest efficiency from this process, the reagents (lime and soda ash) should be added in the proper proportion and thoroughly mixed with the water, the reaction should be accelerated if possible and should be complete. The apparatus should be designed so as to cause rapid sedimentation and perfect clarification. With proper care, particularly incrustaceous waters can be softened to the extent of containing from three to five grains of incrustaceous matter per gallon.

Scale formation is due to the presence of carbonates, sulphates, sediment and mud, and soluble salts in the feed water and its deposition on the inside of boilers not only lessens the available water space but acts as a non-conductor of heat. (It is estimated that 1/16 in. of scale causes a loss of 13 per cent of fuel; ¼ in., 38 per cent, and ½ in., 60 per cent).

To calculate the amount of material that will be deposited in 1000 gal. of water per day, take the number of grains per gallon of each as shown by the analysis and divide by 7; the quotient will be pounds deposited in 1000 gal. of water per day. The scale-forming carbonates in water are those of calcium and magnesium. Both are very sparingly soluble in pure water, but the presence of carbonic acid (CO_2) in the water renders them soluble as bicarbonates; however, carbonic acid is insoluble in boiling water, and is liberated with a consequent precipitation of calcium and magnesium carbonates which tend to deposit as a soft scale. Each grain of calcium or magnesium bicarbonate reported in the analysis as carbonates, requires the number of grains divided by 5.5 expressed in pounds of lime for 1000 gal. of water per day. For example, 5.5 grains of total carbonates requires 1 lb. of lime for 1000 gal. of water per day. The precipitation of carbonates is best conducted in external settling tanks, and particularly so if the carbonates exceed 10 grains per gallon.

The sulphates which are scale forming are those of calcium and magnesium. Magnesium sulphate alone does not form a hard scale, but in the presence of calcium sulphate it forms a very stony scale hard to remove. Calcium sulphate alone forms a hard, tenacious scale. The presence of these sulphates having been determined, soda ash should be used to prevent the formation of the resultant hard scale. However, it is to be noted that the reaction forms sodium sulphate, which, if too concentrated, will produce priming. This condition will be dealt with under the proper head. The quantity of soda ash required may be calculated by dividing the number of grains per gallon of magnesium sulphate by 8 and the number of grains of calcium sulphate by 8.75, and the quotient represents pounds of soda ash per 1000 gal. of water per day. If carbonates and sulphates exceed 15 grains per gallon, external treatment is advisable.

Sediment and mud also cause scale by depositing and baking on the fire sheet of a tubular boiler, the lower tubes in a water tube boiler and the crown sheet in a marine and locomotive boiler.

Soluble salts can also be incorporated in the scale if the concentration is too great. Excess beyond 300 grains per gallon should be avoided.

Corrosion or pitting, which is by far the most dangerous condition met with in boiler practice, may be caused by free acids or substances which develop acidity.

Free sulphuric acid often exists in water and should be neutralized or precipitated. Divide the number of grains of free sulphuric acid by 6.5 and the quotient equals the number of pounds of soda ash required to neutralize 1000 gal. of

water per day. This same rule applies to hydrogen sulphide when present. Under certain conditions it is advisable to use barium chloride or hydroxide and precipitate the barium sulphate externally.

If organic acids exist in the water they have a very corrosive action and can best be corrected by external treatment with alum and soda ash. Divide the organic acidity as reported in grains per gallon in the analysis by 6 to get pounds of soda ash and by 8 to obtain pounds of alum required per 1000 gal. of water per day.

Hydrochloric acid is sometimes found in feed waters and can be corrected by the use of soda ash. The number of grains of free acid divided by 9 equals the pounds of soda ash required for 1000 gal. of water per day.

Magnesium chloride is said to be unstable at high temperatures and in the presence of heated iron and water will split up to form magnesium oxide and hydrochloric acid. The number of grains of magnesium chloride as shown by the analysis, divided by 4.8, equals the number of pounds of soda ash required for 1000 gal. of water per day.

Sodium chloride and silica are said to develop free hydrochloric acid at high temperatures through the formation of sodium silicate. To counteract this effect an alkali such as soda ash must be used. Take the number of grains of available silica present that will act on the sodium chloride and divide by 9.6 and the quotient equals the pounds of soda ash required.

Foaming and priming may be considered under the same head, for both tend to cause wet steam. Priming is due to high surface tension, while foaming is due to matter in suspension.

Sodium sulphate is found whenever soda ash is used to precipitate calcium or magnesium sulphate and is also found in many southern waters. Priming is the result of too great concentration. While the limit of concentration is determined by the type of boiler, the following figures are a close approximation of the truth. Old type two-flue boilers, 1000 grains per gallon, steam at 50 lb. pressure. Horizontal return tubular boiler, 500 to 600 grains per gallon, 100 lb. pressure. Modern water tube boilers, 250 to 400 grains per gallon, steam at 125 lb. pressure. Locomotive boilers, 100 to 200 grains per gallon, steam at 200 lb. pressure.

Sodium chloride also causes priming, but not to such a pronounced degree as sodium sulphate. Usually twice as much sodium chloride can be allowed to concentrate as sodium sulphate without producing priming.

Foaming can be caused through mud and suspended matter and the remedy is either blowing down or filtration.

Sewage and algæ also cause foaming and create a scum on top of the water. This condition may be taken care of either by the use of a surface blow-off or settling filtration.

The subject as here outlined is at best only a brief resume of conditions as met with in boiler practice with reference to the treatment of feed waters, and many cases arise where it is advisable to seek the advice of an experienced chemist or consulting engineer who makes a specialty of water softening.

Bethlehem, N. J.

Decomposition Points of Some Sulphates in an Air Current.

By Walter S. Landis, M. S.

It has been rather disappointing to look in the many new treatises on metallurgy and find such statements as "ferrous sulphate decomposes at a low red heat" or other equally vague statement. This decomposition point of the sulphates is of very great importance in all roasting operations, and very often their occurrence is being forced down our throats (because we would not take it in any other way), and we are expected to plan to utilize a part of our plant as the furnaces themselves, more exact data is wanted on such decomposition points.

The purpose of this work was to determine a few of these decomposition points of the sulphates. The work has already been done without doubt, but the results have never appeared where they are readily accessible, and have certainly not been copied in our more recent books. This determination was not made with the great accuracy that the physical chemist might desire, but rather more to simulate the actual conditions existing in a roasting furnace, that is, in a current of air such as would pass over the materials in a roasting furnace.

The method employed was to insert a porcelain boat, carrying the sulphate in a porcelain combustion tube, into a combustion furnace. Lying on the surface of the sulphate in the boat was the hot junction of a Le Chatelier thermo-couple, previously carefully standardized, the cold junction being in melting ice. Connected to the one end of the combustion tube was a three-mouthed bottle containing a solution of caustic soda carefully neutralized with sulphuric acid, using methyl orange as an indicator. The connecting tube ended in a glass tube dipping well below the surface of the liquid in the three-mouthed bottle. Through the central mouth passed the stem of a separatory funnel, in the bulb of which was placed a dilute solution of caustic soda. Finally the third mouth of the bottle was connected with an aspirator for producing the necessary air current through the apparatus. As decomposition took place the SO_2 and SO_3 passed along with the air current into the liquid in the bottle and affected the indicator. The introduction of caustic soda from the separatory funnel allowed of this acid being neutralized and served to keep the apparatus in continuous working order. Some idea, only qualitative, could be gained as to the rate of decomposition by the amount of caustic soda added to keep the indicating solution neutral.

The results obtained on the sulphates studied were as follows:

$FeSO_4$: The first traces of decomposition showed themselves at 550° C. The increase was but slight up to 580° C and then became more rapid until 600° C. was reached when there was a sudden increase. On heating for two hours at this temperature all decomposition seemed to have stopped as only very slight traces appeared on further heating to 650° C. No further traces were noted between this last temperature and 960° C., the highest temperature attainable in the test.

$CuSO_4$: The first traces of acid appeared at 400° C. Only slight amounts were noted as the temperature was slowly increased to 600° C., when a very rapid evolution took place. A further trace was obtained at 700° C., and then no more up to 900° C., the highest temperature attained in this investigation.

$ZnSO_4$. The first traces of decomposition appeared at 730° C., more appearing at each increase of temperature up to 760° C., when the decomposition was very rapid. All the acid seemed to have been removed at this temperature for no more was found on raising the temperature to 980° C.

In all cases the experiments were repeated several times and gave almost identical temperatures for each stage at each repetition, the points seemingly very markedly characteristic of each salt.

Data of this nature needs no further comment as to its value to the roaster, showing the minimum temperature at which the furnace may be run for complete decomposition and the limits which need not be exceeded for producing the same result.

The Magnetic and Electrical Properties of the Iron-Nickel Alloys.

BY CHARLES F. BURGESS AND JAMES ASTON.

In iron and nickel we have the two most magnetic elements. The fact that a mixture of certain percentages of these two metals results in a non-magnetic alloy makes an investigation of the magnetic qualities of an entire series of these alloys of interest.

There is much literature embodying the results of the research on the irreversibility of certain properties of the nickel-iron alloys and most of the published data of magnetic investigations is concerned with the temperatures of this appearance and disappearance of the magnetic susceptibility for different percentages of nickel.

In the investigation of Barrett, Brown and Hadfield (Jour. Inst. Elec. Engrs., Vol. XXXI, page 674) there is included complete hysteresis loops for a number of nickel-iron alloys in which the carbon runs from 0.13 to 0.23 per cent and the manganese from 0.65 to 1.08 per cent. Also, the magnetization curves of a series was determined by Carpenter, Hadfield and Longmuir (7th Report of the Alloys Research Committee, Inst. Mech. Engrs., Vol. 2, 1905, page 857). In this series the carbon was that of a medium steel (0.41 to 0.52 per cent) and the manganese content varied from 0.79 to 1.03 per cent. These steels, except for the increase of carbon, were almost identical with those of Hadfield, mentioned above; in fact, the work was intended as supplementary to this previous research.

This present paper deals with an investigation of a complete series of iron-nickel alloys in which the endeavor has been to keep down the impurities to the lowest possible point in order

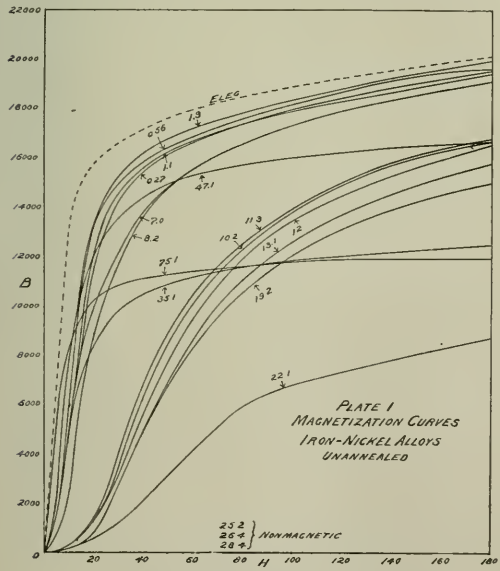

FIG. 1.—MAGNETIZATION CURVES. IRON-NICKEL ALLOYS UNANNEALED.

that the effects observed may be ascribed entirely to the alloying element. The work is part of an extended investigation of electrolytic iron and its alloys carried out during the past several years at the chemical engineering laboratories of the University of Wisconsin, under a grant of the Carnegie Institution of Washington.

The iron used is of a high degree of purity obtained by a process of double electrodeposition. The electrolytic material has a purity represented by an iron content of 99.97 per cent, the total content of sulphur, phosphorus, manganese and silicon being thus 0.03 per cent. The alloys were prepared by melting this iron with the desired quantity of nickel, also electrolytic material of a high purity, in magnesia crucibles supported by a graphite jacket. The crucibles were covered with a magnesia and a graphite lid and buried in an electric resistor furnace in which the melting was done. The resulting ingots

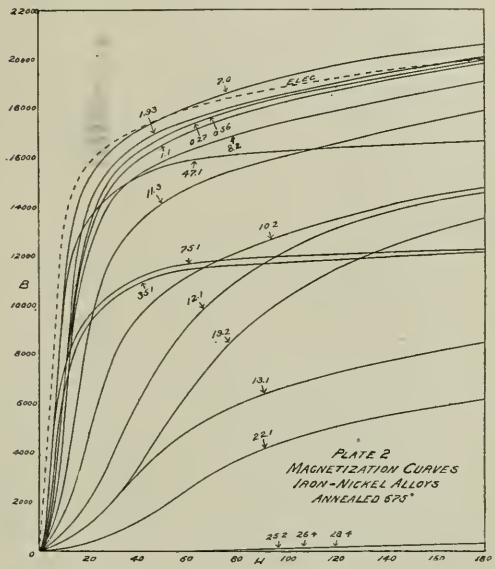

FIG. 2.—MAGNETIZATION CURVES. IRON-NICKEL ALLOYS ANNEALED 675°.

of about 500 grams (1 lb.) in weight, were heated in a forge fire and drawn down under a steam hammer into rods about ⅝ in. in diameter and 18 in. long.

Experience has shown that, in spite of every precaution, there is a slight carbon absorption, unquestionably due to the reaction of the iron upon the carbon monoxide atmosphere of the furnace. The amount, however, is small, and may be assumed in most cases to be well under 0.10 per cent. The other impurities, such as silicon, sulphur, phosphorus and manganese, are entirely negligible. In the present discussion the materials may be considered as binary alloys of iron and nickel and the effects to be due to these two elements alone.

Analysis.

The following series was subjected to magnetic tests.

Bar.	% Nickel— Added.	Analysis.	% Carbon.
144C	0.25	0.27	
144D	0.50	0.56	
144E	1.0	1.07	
144F	2.0	1.93	
144J	7.0	7.05	
157A	8.0	8.17	
157D	10.0	10.20	
157E	11.0	11.29	
157H	12.0	12.07	
144M	13.0	13.11	0.088
144P	19.0	19.21	
166G	22.0	22.11	
154S	25.0	25.20	
166I	26.0	26.40	
166C	28.0	28.42	
166L	35.0	35.09	
166O	50.0	47.08	
166Q	75.0	75.06	

As will be seen, iron and nickel alloy readily and without segregation, since the agreement is strikingly close between the added percentage and that found upon analysis. This evidence is more conclusive when it is remembered that the analyses

were made from turnings during the machining of test bars and after the forging of the ingot.

From the rods forged from the ingots, bars were reserved for tensile strength and one was taken for the magnetic tests. The latter was finished to a diameter of 1 cm with a length of about 20 cm. No sample of pure nickel was tested, since it was impossible to forge the ingot into a bar. It was possible

This instrument was selected because of its adaptability to the work on the several hundred bars on hand and in prospect. It has given good satisfaction in its present form, both as regards rapidity and consistency. The results are not based upon an absolute measurement and the instrument must be calibrated against a standard determined by ballistic test. In our tests, magnetization curves were taken by the method of reversals

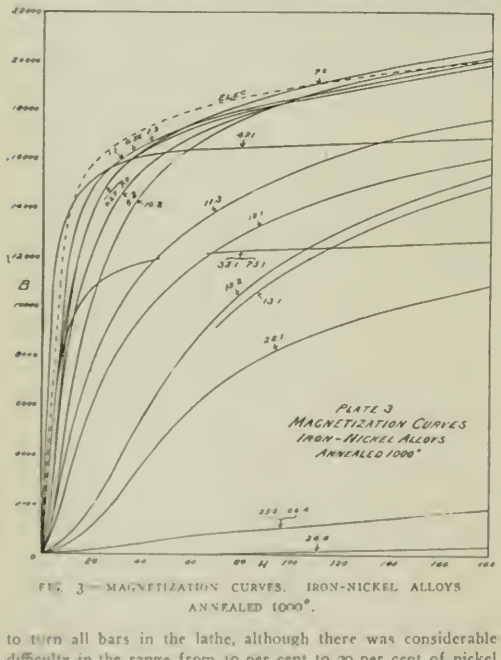

FIG. 3—MAGNETIZATION CURVES. IRON-NICKEL ALLOYS ANNEALED 1000°.

to turn all bars in the lathe, although there was considerable difficulty in the range from 10 per cent to 20 per cent of nickel because of the hardness.

Magnetic Tests.

The magnetic tests were made upon an Esterline permeameter. This instrument is essentially a small generator, the armature of which is driven at a predetermined constant speed. The voltage generated is proportional to the magnetic flux through the armature, since all factors are constant except this flux. The total number of lines of force is equal to that in the bar under test, since this bar forms part of the magnetic circuit. The necessary rheostats and switches are provided for regulation and reversal of the magnetizing current, for compensation, etc. But one recording instrument is used—a Weston millivoltmeter, calibrated to read directly, without calculation, the flux density B and the magnetizing force H in C.G.S. units.

and hysteresis loops by the step-by-step process. Complete magnetization curves and readings of the retentivity and the coercive force were taken under four different heat treatments, first, as forged; second, after heating to 675 deg. C and slowly cooling; third, after heating to 1000 deg. and slowly cooling, and fourth, after heating to 900 deg. and quenching in water.

The results of the magnetic tests are given in Tables I and II and in the curves of Plates 1, 2, 3 and 4. For purposes of comparison, there is given in each plate a dotted curve, plotted from the data of a test on a bar of electrolytic iron in the unannealed state, and which is of very high magnetic quality. The effect of the increase in the percentage of nickel is very apparent. In the unannealed state the alloys fall into several groups. Bars 144C, 144D, 144E and 144F, with 0.27, 0.56, 1.07 and 1.93 per cent of nickel, are very close together, and but little inferior to the standard. Increase of the nickel to 7.05 and 8.17 in bars 144J and 157A, has resulted in a falling off in quality. This is still greater for 157D (10.20 per cent), 157E (11.29 per cent), 157A (12.07 per cent). 144M (13.11 per cent) and 144P (19.21 per cent), which have a low permeability, and the curves of which take positions in the order of the nickel content. The quality of bar 166G, with 22.11 per cent, has become very poor, and finally bars 154S (25.20 per cent), 166I (26.40 per cent) and 166C (28.42 per cent), have become non-magnetic. Further increase of nickel content in 166L, 166O and 166Q, with 35.09, 49.08 and 75.06, has restored the magnetic quality very markedly, the maximum values being reached with 166O (47.08 Ni). Below the saturation bend of the curves (at about H = 40) these three bars have a very high permeability, but beyond this point the permeability becomes practically unity, with the flux density increasing but little more than the increase in the value of the magnetizing force. This latter feature is even more marked after the subsequent annealings at 675 deg. and 1000 deg.

Annealing at 675 deg. has resulted in general in an improvement of magnetic quality throughout the entire range. This is most marked for 144J, with 7.05 per cent Ni, and 157E, with 11.29 per cent Ni. On the contrary, there has been a deterioration in bars 144M (13.11 per cent), 144P (19.21 per cent) and 166G (22.11 per cent); this is very pronounced in the case of the first of these. A very slight amount of magnetism has been induced in the three non-magnetic bars 154S, 166I and 166C.

The second annealing at 1000 deg. has for those bars with smaller nickel content resulted in an increase of permeability for the lower magnetizing forces, with but little change in the upper ranges. Very pronounced changes have taken place in

bar 157D, with 10.20 per cent Ni, which is better throughout, as are bars 157H (12.0 per cent), 144M (13.11 per cent) 144P (19.21 per cent) and 166G (22.11 per cent). The permeability of bar 166O, with 47.08 Ni, has become very high at the lower values of H; in fact, it is about the highest of any of the materials tested in this work. Bars 154S (25.20 per cent) and 166O (26.40 per cent) have become appreciably magnetic.

Quenching at 900 deg. has not resulted in much change, except for the alloys with 11.29 per cent, 12.07 per cent, 13.11 per cent and 19.21 per cent of nickel (157E, 157H, 144M and 144P) where the permeability has greatly increased.

Referring to Table II, the retentivities tend to decrease as we increase the nickel to the compositions of the non-magnetic alloys; and the values of coercive force increase. Beyond this composition the retentivities are again evident, and the coercive forces are small. This is in line with the deductions drawn from the curves and data. In general the coercive forces become smaller with each succeeding heat treatment. For the smaller nickel percentages of 0.27 and 0.56, in bars 144C and 144D, the values 4.3 and 4.2 are about those of electrolytic iron;

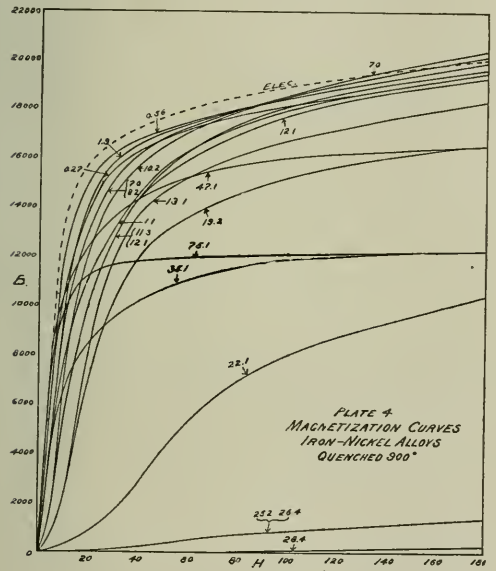

FIG. 4.—MAGNETIZATION CURVES. IRON-NICKEL ALLOYS QUENCHED 900°.

and the values of coercive force for the three bars with the maximum content of 35.08, 47.08 and 75.06 per cent are markedly low.

The alloys with medium percentages of nickel (10 per cent to 20 per cent) seem to be very susceptible to heat treatment, and are at their best after quenching. This might be explained from the fact that nickel has a tendency to lower the temperature of transition in the iron from the hard γ to the soft α form. Consequently, while slow cooling would result in γ state, with its hardness and low permeability, the quenching, with cooling at lower temperatures, might have a tendency toward transition to the α form, with a resultant softness and better magnetic quality.

The strange feature of this nickel-iron series is that with two highly magnetic materials we can obtain all degrees of magnetization, even to a non-magnetic range. Equally striking is the fact (not here investigated) that these alloys in the non-magnetic range at normal temperatures become strongly magnetic at lower temperatures which are dependent upon the composition. They remain magnetic upon a rise of temperature of several hundred degrees, when they again become non-magnetic. Many attempts have been made to explain this anomaly, the reasons being based largely upon allotropy in the two elements.

The behavior is such that one might almost suppose that in the molecular arrangement of the alloys the iron and nickel

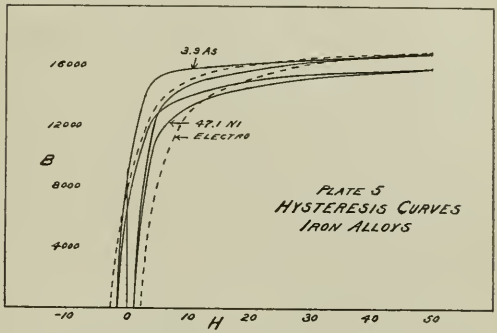

FIG. 5.—HYSTERESIS CURVES. IRON-ALLOYS.

become so oriented as to be of opposing polarity; this opposition becoming more pronounced with increase of the nickel content until finally a balance is reached with the resulting non-magnetic alloy. A further increase of nickel upsets this balance in favor of the nickel with its polarity preponderating.

In the range of commercial usage with 2 to 4 per cent of nickel the magnetic properties of the alloys have not fallen off to such an extent as to obviate against the use of the nickel in case the resulting mechanical qualities required are of sufficient importance to warrant its selection.

Hysteresis.

In connection with the magnetic tests, hysteresis curves were taken on such alloys as showed high permeability, especially such as had low magnetizing forces, and in consequence seemed particularly adapted to transformer working.

In the tests the cycle was carried to a maximum magnetizing force of $H = 50$. Typical bars with low hysteresis losses are noted in the following table; all were annealed at 1000 deg C.

Bar.	Per Cent Composition.	Relative Area of Loops.
117A	Electroforged	1.00
NSW	Swedish anode	1.08
55D	0.067 Al.	1.10
113D	3.862 As.	0.58
123C	1.033 Co.	1.20
166O	47.080 Ni.	0.53
96H	4.655 Si.	0.76
121J	2.059 Sn.	1.01

The results of the measurements upon bar 166O (47.08 per cent Ni) are plotted in Plate 5, together with those on electrolytic iron bar 117A, which was used as the standard of comparison, and 113D with 3.86 arsenic, which latter material showed the highest magnetic quality of any sample tested. The half-loops only are given.

In the above table is noted the relative area of the loops compared to the standard 117A as unity. These figures are indicative of the relative hysteresis losses per cycle of the materials in question. In our tests, therefore, the 50 per cent nickel alloy had the lowest loss, but 53 per cent of the standard and exceeded even the arsenic bar where the loss was 58 per cent of the standard. However, the great cost of this large quantity of nickel would eliminate its extensive use in general practice; also it is in reality not so good a material as some of the other alloys which have but sightly higher loss per cycle and which reach values of flux density considerably higher than the nickel bar for the same magnetizing forces.

Electrical Resistance.

As a study concomitant with that of the magnetic properties

the electrical resistance of the bars of the nickel-iron series was determined. The measurements were taken by the fall of potential method by recording the drop across a measured

166G	22.11	38.7	3.20
144S	25.20	63.2	5.22
161I	26.40	65.5	5.41
166C	28.42	82.0	6.77
166L	35.09	81.1	6.70
166O	47.38	41.7	3.69
166Q	75.06	22.1	1.83
	100.00	12.4	1.02

There is a gradual increase of resistance with the increase of nickel up to a percentage of 22.11, where there is a sudden rise in the curve at temperatures corresponding to those of the austenitic alloys. However, the curve continues to rise, reaching a maximum in the range between 28.42 per cent and 35.09 per cent. At these two points the resistances are respectively 82.0 and 81.1 microhms per cu. cm. or 6.77 and 6.70 times the resistance of the standard. Beyond this range the two determinations made indicate a fall of resistance with increase of nickel in a curve very similar to that on the other side of the maximum range. The final point of the curve at a nickel content of 100 per cent is taken from a standard handbook. Maybe not the maximum point in this curve of resistance but at 35 per cent of nickel, corresponding to the compound Fe_2Ni? Measurements of other kinds, such as dilatation, indicate a change of properties at this composition and tend to support the above view.

Chemical Engineering Laboratories, University of Wis

Current Densities and Energy Losses in Electrodes.

By Jakob Forssell, Ph.D.

At the meeting of the American Electrochemical Society in Philadelphia, May, 1907, a paper on "carbons for electrometallurgy"[1] was read by F. A. J. FitzGerald and the writer. It was our intention at that time to continue our investigation of this subject in order to obtain a full knowledge of the influence and the relations of the different properties of carbon electrodes with regard to energy losses and current densities in electrodes. The paper by Mr. FitzGerald on "the heat conductivity of carbon"[2] read at the meeting of the society in New York, October, 1907, was another contribution to the series of researches contemplated.

In order to obtain a basis for further work along these lines the writer of this article attempted at that time to carry out a theoretical analysis of the different factors influencing the energy losses in electric furnace electrodes. The results obtained from this analysis seemed to offer a very promising guide for the experimental work. However, for various reasons this work was interrupted. The general conclusions derived from the theoretical treatment of the subject as given below were demonstrated and discussed in a paper on "some principles regarding the construction of electric furnaces" read by the writer on Oct. 8, 1908, before the Chemical and Metallurgical Section of the Swedish Association of Technical Societies in Stockholm.

Now that the work on this subject has been taken up again by Mr. C. A. Hansen[3], it seems to the writer that a publication of his calculations may be of interest, since the results obtained by Mr. Hansen appear as logical consequences of these theoretical calculations, thus tending to confirm their correctness. The value of this analysis of the problem regarding energy losses and current densities in electrodes, however, extends far beyond an interpretation of this special case. It gives a general understanding of the relations of the different factors influencing the working of furnace electrodes under different conditions and therefore may serve as a useful aid in the construction of electric furnaces and in suggesting further valuable and necessary experiments regarding electrodes.

In dealing with the problems of energy losses in furnace electrodes it will be necessary to consider the conditions in furnaces of different types. We will, therefore, first take up the question with regard to such furnaces where the electrode enters the furnace through an insulating medium or wall, as shown in Fig. 1. This is the case, for instance, in a number of resistance furnaces.

The general arrangement assumed is evident from the cut. The energy waste consists of two main parts, i. e., heat generated in the electrode by the electric current and heat conducted away from the charge into the electrode. It is disposed of by conduction to the cable connection and by the cooling influence of the atmosphere surrounding the protruding part of the electrode. Further, some heat will also be conducted away by the wall surrounding the electrode.

In order to carry out an exact analysis of the energy losses in the terminal, we would have to know, not only all its dimensions and working conditions, but also the mathematical expressions for the electric resistivities of the materials of the electrode and of the surrounding wall and for the thermal conductivities of said materials as functions of the temperature. Even if we possessed such a knowledge the deduction in this way of the energy losses incurred would lead to a very complicated expression, unhandy for practical use and undoubtedly requiring empirical modifications in its practical applications. It, therefore, seems more rational to carry out our first analysis while assuming certain simplified conditions and to introduce afterward such corrections as are required.

[1] Trans. of Am. Electrochem. Soc., Vol. 11, p. 117.
[2] Trans. of Am. Electrochem. Soc., Vol. 12, p. 161.
[3] Trans. of Am. Electrochem. Soc., Vol. 15, p. 270.

The assumptions made are:

1°. No exchange of heat takes place between the electrode and the surrounding wall.

2°. The electric current is confined to the electrode, no leakage into the surrounding wall taking place.

3°. The electric resistivity and the heat conductivity of the electrode are constant and independent of the variations of temperature.

4°. A uniform temperature prevails in each cross-section of the electrode.

We will use the following notation:

A = area of cross-section of terminal in sq. cm.
I = current in amperes.
a = length of terminal inside of the furnace in cm. (from E to B in Fig. 1).
l = length of terminal outside the furnace in cm. (from B to C).
d = current density in amperes per sq. cm..
t_1 = temperature of terminal in a section through E.
t_2 = temperature of terminal in a section through B.
T = temperature drop between E and B $(= t_1 - t_2)$.
Q = heat conducted from charge through the section at E into the electrode (in watts).

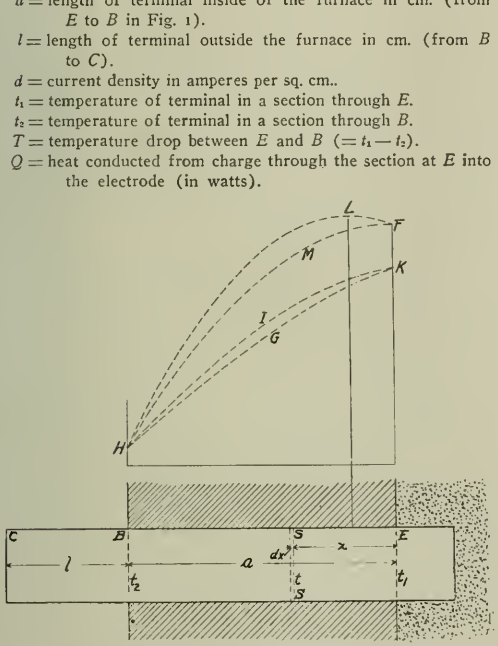

FIG. 1.—HEAT FLOW AND TEMPERATURE DROP IN FURNACE ELECTRODES.

W_1 = power in watts lost by heat conduction from the charge and on account of the electrical resistance of the terminal between E and B.
W_2 = power in watts lost on account of the electrical resistance of the outside part (from B to C) of the terminal.
h = heat conductivity of terminal.
r = electrical resistivity of terminal (per cm. cube).
k = heat equivalent of one watt (= 0.24 cal.).

The variables t and x signify the temperature t in a certain cross-section of the electrode at a distance x from the inside of the wall (E).

We will regard the quantity of heat passing through an imaginary, very thin slice of the terminal at the cross-section $S - S$. The thickness of this slice is dx and the temperature difference between its sides dt. The heat passing through it consists of the heat lost from the charge $(= kQ)$ and the heat produced by the electric current from S to E $(= krxI^2/A)$. Since the temperature difference between the sides of the slice, its thickness and area are known, the heat passing must also be equal $-hAdt/dx$. We obtain consequently the following differential equation:

$$-hAdt/dx = kQ + krxI^2/A \qquad (1)$$

By integration and from the facts that

$$t = t_2 \text{ for } x = a$$

and

$$t = t_1 \text{ for } x = o$$

and further

$$t_1 - t_2 = T$$

we obtain:

$$hA\,(t_1 - t) = (hTA/a - \tfrac{1}{2}\,kraI^2/A)\,x + \tfrac{1}{2}\,krI^2x^2/A \qquad (2)$$

$$Q = hTA/(ka) - \tfrac{1}{2}\,raI^2/A \qquad (3)$$

Equation (2) gives the temperature t in any section at a distance x from E. It represents a parabola with vertical axis.

The temperature drop per cm. (dt/dx) in any such section we obtain by derivation of equation (2):

$$-hAdt/dx = hTA/a - krI^2(a/2 - x)/A \qquad (4)$$

The left-hand term expresses the amount of heat passing through a given section at the distance x from E. The total loss of energy in watts in the part of the terminal inside the wall (E to B) by conduction from the charge and from the heat generated by the current we find by inserting a for x. We thus obtain:

$$W_1 = hTA/(ka) + \tfrac{1}{2}\,raI^2/A \qquad (5)$$

If no electric current was flowing through the electrode, the energy lost by conduction of heat from the charge into the electrode would amount to $hTA/(ka)$ watts, but on account of the current heating the terminal, the energy lost by conduction from the charge into the electrode is decreased by an amount equal to one-half of the heat generated by the current in the terminal. Thus we find that the heat generated by the current serves a useful purpose in keeping down the loss from the charge.

We will now consider the influence of the assumptions made in these deductions. According to our first assumption no exchange of heat should take place between the electrode and the surrounding wall. This condition will usually not be fully satisfied in practical working. However, as this subject will later be discussed at some length, it may at present be sufficient to say that the corrections to be made on this account will, as a rule, not affect our results very materially.

Regarding our second assumption that the current should be confined to the electrode, no leakage through the wall taking place, it probably in most cases answers the conditions in practical working so nearly that no corrections on this account are needed. One point should be raised, however, in this connection concerning the value assigned to the length a of the electrode. The electrode frequently enters the charge for some distance, the current in the meantime branching off into the charge. The current density will therefore gradually change in this part and the conditions assumed in our calculations will not be fulfilled. Therefore, the inside length of the electrode a should strictly be counted only to the point where the current begins to branch off into the charge. For practical purposes, however, it will be better to include also about one-half of the projecting end into the length a of the electrode.

The third assumption regarding the constancy of the conductivities of the electrode for heat and electricity is not fulfilled in practical operation, since, as well known, both increase to some extent with increasing temperature. By using mean values between the temperature limits the error which is committed will, however, be considerably reduced.

In this connection it is of interest to discuss somewhat in detail the distribution of temperature in the electrode. As already stated the heat passing through each section of the electrode will consist of the heat conducted away from the charge plus the heat generated by the current due to the resistance of the electrode between this section and the inside end of the electrode. As the distance from the inside end to the section under consideration increases, the total amount of heat passing through the section will, therefore, also increase. In order to render possible the passage of this increasing quan-

ity of heat, the temperature drop per centimeter must increase correspondingly. If the conductivities for heat and electricity of the electrode are constant, the temperature curve thus will assume the form of a parabola as shown (equation 2).

However, when these conductivities increase with increasing temperature, as is actually the case, the conditions are somewhat changed. We will still assume that no exchange of heat takes place between the electrode and the surrounding medium. If the working conditions are the same as in our first case (with constant conductivities) and the same amount of heat is conducted away from the charge, a smaller temperature drop per centimeter will now be needed at the inside end of the electrode to dispose of this heat. The amount of heat generated by the current per unit length of the electrode in this end will also be smaller than in the first case discussed, on account of the higher electric conductivity, and the increase in the temperature drop per centimeter, when gradually moving our point of observation from the inside end of the electrode, will consequently be correspondingly smaller, although growing also on account of decreasing heat conductivity. At a certain section of the electrode its conductivities for heat and electricity will correspond to the mean values assumed in the first case which we discussed.[1]

However, the amount of heat passing through this section is smaller than in the first case on account of the lower resistance of the inside part of the electrodes, and consequently the temperature drop in this section will still be smaller than in the first case. When passing further outwards the amount of heat generated by the current per centimeter of the electrode will now be larger than in the first case, due to the higher electric resistivity, while the lower heat conductivity also contributes to a more rapid drop of the temperature curve. Since the total electric resistance is the same in both cases (on account of our adoption of the mean value[2] as resistivity of the electrode in the first case) the same total amount of heat would be lost through the section at the outside end of the electrode in both cases.

In the second case the temperature drop per centimeter in this section, as well as in the part of the electrode near its outside end, will consequently be greater than in the first case. However, it is impossible to foresee, without an exact knowledge of the values of the conductivities at different temperatures, whether the temperature curves of the electrode would indicate the same temperature of the electrode in both cases at the outside of the wall. However, by defining the mean value of the heat conductivity in the first case in a special way with regard to calculations concerning electrodes, the temperatures of the electrode at the outside end will be identical in both cases. Curves *K-G-H* and *K I H* in Fig. 1 will give a general idea about the run of the two curves discussed.

The determination of the mean value of the heat conductivity as usually made by measuring the amount of heat conducted through an object while a constant temperature difference is maintained between its ends, will give values not suitable for our purposes.

When determining the electric resistivity of electrodes for practical purposes we measure the voltage drop and the current strength in working electrodes. The value thus obtained is not, however, the mean resistivity for the material of the electrode between the temperature limits occurring. If the latter was to be measured strictly the determination should be carried out with an electrode exposed only to a constant temperature difference, but not to a simultaneous heating by a current, using, for instance, a current too weak to influence the temperature distribution in the electrode. However, a value thus obtained would not be of practical usefulness for our purpose.

The same considerations apply when measuring heat conductivities of electrodes. In order to get values which may be directly applied in practical calculations, it will be preferable to carry out the measurements under practical conditions.

It was originally the intention of the writer to determine such values from experimental data by the aid of equation (5). For instance, an electrode (Fig. 2) may be surrounded by a highly refractory and well-insulating powder, such as magnesia. The waterjacket of the contact serves as calorimeter and the flow of water is regulated so that the temperature of the upper end of the electrode is the same as the temperature of the insulating packing at the same depth. The temperature of the electrode is also increased by means of a thermo-couple as far down as the couple will permit (1400° C.).

Under these circumstances the conditions assumed in equation (5) will hold with sufficient accuracy, and all measurements necessary for calculating from equation (5) the mean heat conductivity of the electrode may easily be made. By using such methods (properties of carbon) for determining the very high temperature of the hot end, as described by Fitz-Gerald (Trans. of Am. Electrochem. Soc., Vol. 6) and by Hansen (ib. Vol. 15) the total temperature drop in the electrode may, of course, be extended to much higher ranges.

From the nature of these methods for determining the mean

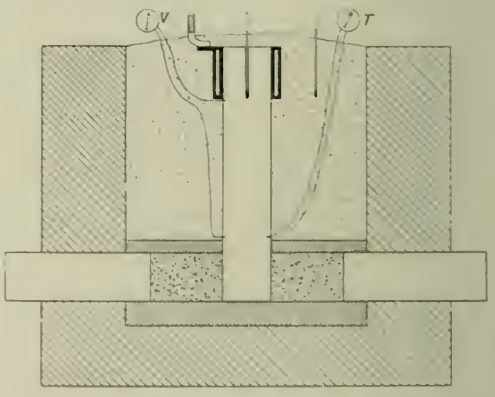

FIG. 2.—ARRANGEMENT OF TEST

conductivities for heat and electricity, it follows that by using such values no considerable error will be introduced on account of our third assumption regarding the constancy of these conductivities.

Our fourth assumption that a uniform temperature prevails in each cross section of the electrode will in most cases have only a small bearing on our deductions. At both ends of the electrode the isothermic surfaces will, of course, be somewhat disfigured, but for the greatest part of the electrode they will at least have a uniform shape and probably, as a rule, come close to being flat surfaces with some curving at their peripheries.

From this discussion of the assumptions involved in our deductions and the definitions made we have found that the energy loss, expressed by equation (5), will in certain cases probably correspond closely to actual conditions. The most serious objection to its correctness depends upon the assumption that no heat should be conducted away from the electrode to the surrounding wall. When this is the case the loss will be greater than indicated by the equation.

However, we may claim that the largest possible loss of energy from the charge into the electrode would occur if the heat produced by the electric current did not cause any decrease in the amount of heat which would be lost by conduction from the charge into the electrode in case no current was flowing.

[1] We assume that the graphic [illegible] of the curves in these conditions is identical of the [illegible] are the same.

[2] The [illegible] of the mean value is supposed to have been made by measuring voltage drop and current strength in working electrodes.

Such a case may be imagined if the surrounding wall would cause a sufficiently strong cooling of the electrode. The total loss would then amount to:

$$W_1 = hTA/ka + raI^2/A \qquad (6)$$

As evident, the only difference between equations (5) and (6) consists in the fact that in the first-mentioned case the term raI^2/a is multiplied with the factor $\frac{1}{2}$. We will now substitute for this factor a coefficient c, the value of which may, according to the working conditions of the electrodes, vary between the limits $\frac{1}{2}$ to 1, and consequently write the equation thus:

$$W_1 = hTA/ka + craI^2/A \qquad (7)$$

where h and r express mean values, as defined, with regard to our temperature range.

This equation, therefore, represents a general solution of the problem of energy losses of electric furnace electrodes independently of any assumptions regarding heat insulation of the electrode.

Regarding the value of c we have so far only stated that it is between $\frac{1}{2}$ and 1. Its exact value in each special case will depend upon a number of considerations.

The first condition for a transfer of heat from the electrodes to the surrounding wall is that there should exist a temperature difference between them at their places of contact. In this conection we must remember that the wall is also heated by conduction from the charge.

At the inside of the furnace wall its temperature will, therefore, be about the same as that of the electrodes, no exchange of heat taking place between them at this point. On its outside the furnace wall will assume a certain temperature. Here the temperature of the electrodes will depend upon the cooling effect of the contact plates, the holder, and, possibly, the water-cooling applied. If water-cooling is used, this temperature may easily be the same as that of the wall, or close to it. In such a case there will be only a very small exchange of heat between the terminal and the wall, depending upon the difference in their temperature distribution and c will therefore have a value of practically $\frac{1}{2}$.

However, if the temperature at the outside of the terminal is considerably higher than that of the wall we must figure with a certain transfer of heat from the terminal to the wall. Another circumstance, in conjunction with the higher heat conductivity of the terminal, will offset to some extent this transfer, namely, the fact that the heat passing from the terminal to the wall will have to travel a longer path than that going directly through the terminal. Besides, there is always a contact-resistance against the transfer of heat from the terminal to the wall.

The amount of heat conducted away from the electrode to the wall will also depend upon the relation between the circumference of the electrode and its cross-section and the relation between the heat conductivities of the material of the electrode and of the surrounding wall. It is obvious that this heat quantity will be larger the larger the circumference of the electrode is as compared with its cross-section. From this fact we may conclude that in case of electrodes with uniform cross-sections, working with the same current densities and otherwise under the same conditions, the one with a larger cross-section will cause a relatively smaller energy loss and consequently give a smaller value for c.

It is also evident that the shape of the cross-section has in the same way an influence upon the energy loss incurred. Of electrodes with the same cross-sections, working under the same conditions, a round electrode will cause the smallest loss. Of rectangular electrodes a square electrode will give the most favorable results in this respect. The more the cross-section of an electrode is extended in one direction the greater will be the loss by conduction to the wall. As an extreme case we may state with great probability that if h is the heat conductivity of the electrode and h_w the heat conductivity of the wall, the value of c, derived from the following equation:

$$c = \frac{1}{2}\left(1 + \frac{h_w}{h}\right) \qquad (8)$$

will represent an upper limit of the possible value of c.

If, therefore, the relation between these conductivities is 1 to 5, as probably in the case with amorphous carbon electrodes, made from petroleum coke, when laid in brick walls, c would probably have a highest possible value of 0.60. If graphitized electrodes are used under the same conditions, the relation of the conductivities would be at least 1 to 40 and c consequently have a highest possible value of 0.51.

If the circumference of the electrode is p (A being its cross-section), the formula given for c will apply when p/A has a high value, i. e., in case of very small electrodes. On the other hand, if p/A has a small value, as is the case with large electrodes, especially of a compact cross-section, c will assume a value tending to approach $\frac{1}{2}$. For commercial furnaces the value of c will therefore probably be located closer to $\frac{1}{2}$ than to the value found from equation (8).

Although in this way c is shown to be a function of two variables, i. e., the cross-section and circumference of the electrode, the possible variation of c appears to be comparatively small. Instead of attempting to introduce into our calculations an expression for c (for instance, $c = \frac{1}{2}[1 + h_w p/(hp + hfA)]$ where f is a constant) so as to take into account the considerations presented, thus complicating our deductions and conclusions in a high degree, we will therefore attribute a constant value to c, depending upon the type of the furnace and, within certain limits, upon the size of the electrode.

In order to give equation (7) a form more suitable for our deductions we substitute for A the expression: $A = I/d$ and thus obtain:

$$W_1 = I\,(hT/(kad) + crad) \qquad (9)$$

It should be noted that this energy loss is expressed in watts. As the current I is one factor in this expression it follows that the other factor represents the *total voltage loss* in the inside part of the electrode, due to the combined loss of energy by heat conduction from the charge and on account of the resistance of the electrodes.

As the total loss of energy W_1 consists of the sum of the loss on account of the resistance of the electrode $radI$ and the loss by heat conduction from the charge Q (i. e., the heat conducted from the charge into the electrode) we may get an expression for the last mentioned loss by means of equation (9):

$$Q = I\,[hT/(kad) - (1 - c)\,rad] \qquad (10)$$

Evidently, by using a certain current density, the conduction of heat Q from the charge into the electrode may be entirely avoided. This is the case if:

$$d = \frac{1}{a}\sqrt{\frac{hT}{kr\,(1-c)}} \qquad (11)$$

The electrode loss, when no heat is conducted away from the charge, amounts to:

$$W_1 = I\sqrt{hrT/k\,(1-c)} \qquad (12)$$

As the electrode loss in this case is caused only by its electric resistance, we may also express this loss in the following way:

$$W_1 = radI \qquad (13)$$

This expression may, of course, also be deduced from a combination of equations (11) and (12).

From equation (9) we also conclude that the total electrode loss will have the smallest possible value for a certain value of the current density. This value is:

$$d = \frac{1}{a}\sqrt{\frac{Th}{ckr}} \qquad (14)$$

The smallest possible loss, therefore, amounts to:

$$W_1 = 2I\sqrt{Tchr/k} \qquad (15)$$

We have considered so far only electrodes surrounded by an insulating wall. However, it is well known that electrodes may

enter the furnace also in other ways. Thus they may be suspended vertically in the furnace and the charge fed down around them, as in the case, for instance, in carbide or ferrosilicon furnaces. In other cases, for instance, in the steel furnaces of Heroult and Girod, the electrodes enter the furnaces through openings in an arched roof and do not come into direct contact with the charge.

In the first-mentioned case our formula may usually be applied. The surrounding charge will, as a rule, conduct more or less electric current. Its resistance, however, will be considerably higher than that of the electrode and, besides, the contact resistance between the terminal and the charge will prevent to a great extent a spreading of the current into the upper layers of the charge. The electric conductivity of the charge will, therefore, as a rule, not constitute any serious objection to the use of our formula.

Regarding the question of heat losses from the terminal to the surrounding charge we must consider the fact that any heat possibly given off from the terminal to the charge will preheat the charge and, therefore, cannot be charged as a loss.[1] At the same time it is of greatest importance that no heat should be conducted away by the terminal from the zone of highest temperature at its lowest end. This will depend upon the temperature distribution in the electrode.

At the lowest end of the electrode, where reduction and melting of the charge takes place, highly heated gases are formed which pass upwards through the charge around the terminal. These gases are therefore cooled and their heat is absorbed by the charge. In the lower part of the charge, near the end of the terminal, heat is also supplied to a great extent by conduction from the electrically heated zone. The temperature drop per centimeter (counted upwards) will therefore be small in this part. Higher up, where the heat is mostly carried by the gases, the drop will be faster.

It will be remembered from our discussion that in the first case considered the temperature in the electrode varied according to a parabola and that when no heat was lost from the charge by conduction through the electrode, this parabola had its center at the inside end of the electrode. This distribution of the temperature in the terminal, therefore, agrees in its general features with the temperature distribution in the charge as described.

There seems, therefore, to exist no principal objection against the application of our deductions to electrodes in furnaces in which the charge is fed down around the electrodes, due consideration being given in each case to the circumstances which influence the value of c. The drop in temperature T in our calculations represents in this case the temperature difference between the hottest end of the electrodes and the part of the electrodes at the top of the charge and a the distance between these points.

In the third class of furnaces, with electrodes freely suspended, the conditions are much more complicated. Our equations, however, undoubtedly may be applied also in this case. An account of the probable conditions prevailing in these electrodes, however, would involve so many uncertain assumptions that a detailed discussion of this subject may preferably be postponed until experimental data are available regarding the questions involved.

We have so far considered only the losses of the part of the electrodes inside the furnace. The protruding end of the electrodes will, of course, cause an additional certain loss due to its resistance. This loss may be expressed in watts by the following formula:

$$W_1 = rId^2l \qquad (16)$$

The electric resistivity r in this case has a higher value than obtains in the inside part of the electrode due to the lower temperature of the outside part.

As the outside end of the electrode should, from every consideration, be made as short as possible, we will not further enter upon a discussion of equation (16), but limit our deductions to the inside part of the electrode.

We may draw a number of conclusions of practical value from the equations derived. First, however, a general remark deserves attention. We have found that the heat conductivity of the electrode is of exactly the same importance to the working of the electrode as its electric resistivity. The electric resistivity has until recently been practically the only property which has been taken into consideration, both by furnace men and by manufacturers, especially when favorable as a "talking point." With electrodes of different materials, the loss is proportional to the square root of the product of the thermal conductivity h, and the electric resistivity r, other things being equal. If in case of two electrodes, A and B, made from different materials, the electric resistivity of A is only one-fourth of that of B, but the heat conductivity of A is eight times higher than that of B, then the smallest possible loss of energy in A would be 41 per cent higher than the smallest possible loss in B in spite of the lower electric resistivity of A. From the point of view of energy losses incurred, a low electric resistivity is therefore no inducement to the use of an electrode if its heat conductivity is very high.

In discussing the energy losses of electrodes the greatest interest, of course, centers around the equations expressing the most favorable conditions attainable with regard to these losses. Equations (11) to (15) refer to these conditions. It is obvious from these equations that when c possesses the value $\frac{1}{2}$, as probably is often the case, at least approximately the values of the current density d, according to equations (11) and (14), will be identical. In such a case, therefore, the same current density will give the smallest possible electrode loss and, at the same time, prevent any loss of heat from the charge by conduction through the electrode.

If c has a higher value than $\frac{1}{2}$, the electrode loss, equation (14), will be a minimum for a current density with which a certain amount of heat flows from the charge into the electrode. In order to avoid this loss it would, therefore, be necessary to raise the current density to a higher value, according to equation (11). If we assume that c has a value as high as 0.75 this raise of the current density would amount to 73 per cent, while the corresponding increase in the total loss of energy in the electrode would only amount to 15 per cent. If c, however, possesses a more normal value, such as 0.6, the corresponding percentages only amount to 22 per cent and 2 per cent. These figures for the increase of the energy losses, when compared with other losses in the furnace, are so insignificant and the advantages gained from these small sacrifices of energy so important that we may state it as a general rule that if other considerations do not interfere, the lowest current density, as given by equation (11), should be used which will cause no loss of heat by conduction from the charge into the electrode.

This loss will also be prevented if a still higher current density is used, but the total loss of energy will, in such a case, be further increased, as may be seen from equation (9). This case is interesting because it corresponds to certain results obtained by Mr. Hansen. He found in an experiment that the total loss of energy of his electrode was less than corresponded to the Joulean heat of the electrode as figured from its resistance.

It is obvious that the necessary requisite for avoiding any loss of heat by conduction from the charge is that in some section of the electrode there should be no temperature drop (per centimeter). For instance, in case of the electrode in Fig. 1, the tangent of the temperature curve at some point should be horizontal. To accomplish this it is only necessary to use a current density which will produce this turning point of the temperature curve right at the inside end of the electrode; the temperature is then at this end the same as prevails in the furnace (Fig. 1, curve $F_1M_1I_1$). This current

[1] As we use equation for W_1 include also the heat, conducted away by the surrounding medium, these expressions will therefore give somewhat too high values (cf. p. 24) in case of furnaces of this type.

density has been defined by our equation (11). If a higher current density is used, the top point (L) of the temperature curve F-L-H will fall within the wall and the heat generated from electrical energy will flow both ways from L, part of it being lost in the ordinary way, the other part being supplied to the furnace. This consequence of our deductions has been realized in the case of Mr. Hansen's experiment. Although Mr. Hansen was able in this way to get a smaller loss than corresponding to the resistance of his electrode, he nevertheless had a larger loss than necessary. With a somewhat lower current density, it would have been possible to avoid any heat conduction from the charge into the electrode with a smaller energy loss in the electrode.

There is another side to this question. If such a high current density is used that an overheating of the electrode occurs within the wall, the temperature attained will often ruin the wall, with consequent disastrous results to the furnace, certainly a sad experience of many electric furnace workers. On the other hand, if the same condition prevails in a furnace where the charge is fed down around a vertical electrode, the overheating of the electrode may cause a clogging of the charge around it and a wasteful leakage of the current. If in such furnaces two electrodes of different polarity are suspended side by side, the undue conductivity thus imparted to the charge between the electrodes will sometimes cause a short circuit and the current will not pass through the molten bath below the electrodes, as intended.

If we have electrodes with a thermal conductivity h and electric resistivity r, and want to use them in a furnace with a total temperature drop in the electrode T, and a current I, we may assume for practical purposes that c will have a certain fixed value independently of the length a we may give the electrode. Equations (11) and (12) may then be written as follows:

$$d = C_1 \sqrt{T/a} \qquad (17)$$

$$W_1 = C_2 I \sqrt{T} \qquad (18)$$

where C_1 and C_2 are two constants.

The product $C_2 \sqrt{T}$ in equation (18) represents the total voltage loss in the electrode when no heat is lost by conduction from the charge, the current density required for this purpose being given by equation (17). This current density is inversely proportional to the length of the electrode, while the voltage loss thus incurred is independent of the length of the electrode, remaining a constant for a certain total temperature drop in the electrode. A practical application of this rule is that if a certain current density has proved to give the most satisfactory results obtainable in a furnace, we may in this way compute the best value of the current density for another furnace of the same kind but with different length of the electrode. Because this principle has not been recognized there has certainly resulted much distress and surprise on the part of electric furnace men, the troubles being mostly due to the overheating of electrodes, already discussed.

With a certain total temperature drop in the electrode it is, therefore, feasible to incur the smallest possible loss of energy in the electrode whatever the length of the electrode may be, if only the current density is accordingly adjusted. In order to reduce the cost of electrodes, therefore, it would seem rational to use very short electrodes with a correspondingly high current density and to prevent an excessive heating of the outside end of the electrode by water-cooling. Although this method undoubtedly may be used with advantage to a larger extent than practiced so far, its application in most cases is limited by practical considerations.

In furnaces with fixed electrodes, surrounded by a wall, the method may sometimes prove useful if the water-cooled metallic holder is allowed to enter the wall for some distance. However, the risk of burning off the electrode, with all its dangerous complications and the difficulty in making good contact on the inside between the electrode and the charge or perhaps the permanent resistor will limit our endeavors in this direction. Besides, as the cost of the permanent electrodes in this class of furnaces is a comparatively small item, this possibility of using very small electrodes has no great bearing on electric furnace construction.

On the other hand, in many cases, especially with furnaces where the charge is fed down around the electrode, the best current density is dictated not only by electrode considerations, but also by the conditions at the place of transfer of the current from the electrode to the charge, where, as a rule, most of the heat in the furnace is generated. The electrode—its dimensions as well as its quality—should therefore be adjusted largely according to these conditions.

If a current density too high for the purpose of the process is used, the heat generated here may be too excessive to be usefully disposed of. Parts of the charge may be needlessly volatilized, products, already formed, may be decomposed, and undesirable reactions may take place. Besides, in such a case the electrode itself will be attacked and consumed to a much greater extent than necessary. It is probably a fact that from considerations to the first cost of electrodes a higher current density is used in many cases than consistent with the lowest consumption of electrodes per ton of output.

If we have furnaces of the same kind, but with different temperature drops T in the electrodes, the factors C_1 and C_2 assumed as constants in equations (17) and (18) will no longer remain so. The mean conductivity for heat h and the electric resistivity r will assume different values in the different cases. However, if there is no considerable difference in the total temperature drops we may assume that the relative increase in the mean thermal conductivity will be approximately the same as the relative decrease in resistivity and that, therefore, the agreement of their product will remain practically a constant. Under the same assumption there cannot exist any considerable difference between the values of c. Even if its different values varied as much as, for instance, from 0.55 to 0.60 the increase in the value of $\sqrt{1/(1-c)}$ would only amount to 6 per cent. We therefore find that the value of C_2 in equation (18) may be regarded as a constant for practical purposes when there are no great variations in the total temperature drop. However, the value of C_1, containing as a factor the square root of the quotient of h and r, will be influenced by a change in the total temperature drop to a degree which we cannot determine in advance. The only rule we can give at present for the most suitable current density in case of an increase of the total temperature drop in an electrode of a certain length a is therefore, that this current density should be higher than the one obtained by multiplying the best current density at a lower temperature drop by the square root of the quotient of the larger and the smaller temperature drops.

For the reasons given we may consider that equation (18) will hold with sufficient accuracy also in case of different temperature drops in the electrode within certain limits. As a rule, the inside temperature of a furnace used for a certain purpose is determined by the process worked. A comparison of the losses in the electrodes in case of different processes is therefore not of the same interest as an analysis of the possibilities offered to reduce the loss in a certain case. We have already at length discussed this subject, assuming a constant temperature drop. However, different temperature drops may occur in electrodes, having a definite temperature at their inside ends, on account of different temperatures being maintained at their outside end. Equation (18) may be safely applied to such cases. We may derive some important conclusions regarding the effect of water-cooling the outside end of the electrode upon the loss incurred.

The outside end of an electrode, exposed to the air, must not assume a temperature causing a burning of the electrode. If the protruding end would become red hot without water-cooling, its application is imperative. If the current density used corresponds to the value defined by our equation (11) or

(17), water-cooling in such a case cannot be regarded as causing an additional loss. It would be possible by giving the electrode a greater length and using a lower current density according to equation (17) to produce the same temperature at the outside end without water-cooling, but the loss, incurred in the electrode, would nevertheless be the same in both cases, as shown in our previous deductions.

A temperature drop reaching down to the burning temperature of carbon is unavoidable in any case, and we should, therefore, only charge the loss incurred on account of the additional drop in temperature against the water-cooling applied. This additional drop will, at the most, amount to about 400° C. If the inside temperature of a furnace is 2000° C., and the temperature drops in the electrodes are 1950° C. with water-cooling and 1550° C. without water cooling, then the additional loss, according to the equation (18), on account of the water-cooling, would amount to 12 per cent of the loss without such cooling. If the voltage loss, due to the electrode, is 1 volt without cooling, then the additional loss, caused by its application in this case, would only reach 0.12 volt. Besides, the higher the inside temperature of the furnace is the smaller will be the relative increase of the loss due to the water-cooling.

We therefore find that water-cooling, when applied to electrodes working with proper current densities, does not cause any significant losses. Those incurred are more than compensated for by the benefits.

It may be appropriate in this connection to discuss somewhat the practical advantage of water-cooling, as this subject is closely related to the conditions for the best working of electrodes. The purpose of the water-cooling is not limited to the purpose of preventing the burning of the electrode. Water-cooling is also of the greatest importance for the maintaining of a good contact between the cable connection and the electrode. As well known, such a contact is usually accomplished by firmly pressing metallic contact plates against the electrode. When possible (compare the article by FitzGerald in Vol. 3, 1905, page 14, of this journal) this contact is often improved by placing a layer of graphite between the plates and the electrode. In many cases, however, the application of such a layer is impracticable and the contact resistance produced may therefore be unduly high on account of the combined influence of a high specific contact resistance and of the fact that the plates and the electrode actually touch each other only at a few spots.

Without water-cooling a very strong heating of the contact place may follow, resulting frequently in oxidation of the plates. This increases the contact resistance still more with the consequences of a burning of the electrode and arcing contact. Water-cooling will largely prevent these troubles and therefore serve to keep the electrodes in running order. However, if the contacts have not been carefully made, water-cooling will conceal the bad condition of the contacts and the waste of energy on their account will be, as a rule, attributed to the electrode alone, if recognized at all. This serious cause of energy losses deserves more attention than is usually bestowed upon it.

As an example of the losses sometimes occurring on account of bad contacts, an occurrence within the writer's experience may be cited. The connection to a permanent electrode carrying 1800 amp was made by firmly clamping against two large copper plates with interposed layers of graphite ("decomposed carborundum"), the current density in the contact surfaces being only 11.4 amp per square inch. When the connection was first made, a voltmeter, permitting readings of 1/200 volt, only indicated a voltage drop of about 1.07 volt in the connection. After three runs of the furnace the electrode became excessively hot and on renewed reading of the voltage drop it was found to have risen to 1.47 volt. The voltage drop in the electrode itself amounted to 1.16 volt. This enormous energy loss in the contact was found to be due to a tarnishing of the copper plates from fumes emerging from the furnace. This instance may serve as a caution against similar occurrences of wasteful losses.

A short outline of a simple way to calculate the dimensions of electrodes, based upon the above formulas, may now be of interest.

In a given case the inside temperature of the furnace may be regarded as known. Although this is one of the fundamental quantities for any calculation of this kind, its knowledge is far from satisfactory in most cases on account of our limited knowledge of the temperatures required for the reactions or processes contemplated. Sometimes we may find from preliminary experiments some guide for estimating the temperature required. An examination of the electrode may give important clews, as shown by Mr. Hansen. However, the results obtained in this way must be interpreted with great caution if the experimenter has not an exact knowledge of the quality and composition of the electrode used. Otherwise an extensive investigation of the same kind as carried out by Mr. Hansen will be necessary.

However, we may find other indications of the temperature attained. The carborundum frequently formed on the tips of the electrodes may render such assistance. From the measurements of Tucker and Lampen (compare the synopsis in this journal, Vol. 4, 1906, page 363) we may conclude that the temperature in a given case has been between 1615° C. and 1950° C. if green amorphous carborundum is found on the electrode, but no crystalline carborundum. If crystalline carborundum has been formed, but no crystals of "decomposed carborundum" (graphite) are found, the temperature has been above 1950° C. and probably not exceeded 2220° C., but the graphitizing of the electrode tip does not necessarily indicate a temperature above 2220° C. Some other valuable indications may also be obtained from data given in the original paper of Tucker and Lampen (*Jour. Amer. Chem. Soc.*, July, 1906). It is to be hoped that an extended knowledge of the "chemistry of high temperatures" as well as of the physics of those temperatures will soon give us an exact basis for work of this kind.

Generally electric furnace workers have a tendency to exaggerate the temperatures prevailing in their furnaces. It is a common claim that the charge has been heated to the temperature of the arc, citing 3500° C. to 3700° C. as this temperature, because an arc was drawn in the furnace. The experimenter forgets that said temperature prevails when the arc is extended between electrodes of pure carbon with carbon vapor alone as conductor and not in a furnace usually filled with metallic vapors of comparatively high pressures. Further, the constituents of the charge and the products formed, as a rule, have a high vapor pressure at these temperatures, the sum of which may reach atmospheric pressure, preventing an increase of the temperature on acount of the subliming or boiling which then ensues.

Magnesia, one of our very best refractories, melts at 1920° C. (Goodwin and Maily, this journal, Vol. 4, page 217) and boils at a temperature shortly above its melting point according to Moissan, which statement is confirmed by observations of the author. In most extreme smelting processes we will probably not be far from the truth in assuming that the temperature will be somewhere between 1800° C. and 2200° C. When heating solid charges, such as certain carbides or carbon, the temperature may, of course, run up considerably higher.

When the inside temperature has been determined or estimated in one way or the other, the outside temperature must be decided upon. If water-cooling is used no appreciable error will be committed in placing this temperature at 100° C. Otherwise it may be about 100° C. or 200° C. higher.

The length of the electrode is the next consideration. This dimension will depend upon the working conditions of the furnace, and no general rule can be made for its proportioning except that the length is limited by the technical difficulties in manufacturing (preventing at present the manufacture of amorphous carbon electrodes of greater length than 7 ft.)

When the temperature drop T and the length a are thus fixed, the current density d will be the important object of our attention.

As already stated, the best current density is determined not only by the electrode, but also to a great extent by the purpose of the process worked. With regard to the last mentioned consideration we will usually have some latitude for fixing the current density, and we may therefore first investigate what density is most suitable on account of electrodes of different materials available. In order to do so we have to know the various physical constants of the electrodes and the electrode constant c of the furnace.

With a knowledge of the progressive and scientific spirit of the concerns manufacturing electrodes in the United States, we may confidently hope that they will carry out such investigations as will place to the disposal of their customers the information wanted regarding their electrodes.

For furnaces with an electrode constant c, which has the value $\frac{1}{2}$, we may calculate from equation (12) the voltage drop $\sqrt{hrT/k\ (1-c)}$, which corresponds to the temperature drops T when no heat is conducted away from the charge. Experiments should then be carried out with the same kind of furnace and using the calculated current densities to check whether the energy actually lost corresponds satisfactorily to the quantity calculated from equation (13). If this is the case a very nice check has been obtained for the correctness of the determinations made.

The next step in the investigation required is to determine the energy losses in the electrodes under working conditions of furnaces in order to find the value of c under different conditions.

Such experiments will surely offer certain difficulties, which, however, may be overcome. When the value of c is known in a given case, we may find the smallest voltage drop required in the electrode in order to avoid heat conduction from the charge by multiplying the voltage drop for $c = \frac{1}{2}$ with the correction factor.

Having access to the results of these determinations, the designer may draw a curve showing the smallest voltage drops in the electrode at different total temperature drops, when no heat is conducted away from the charge, assuming the value $\frac{1}{2}$ for c equation (12).

In a given case in practice, characterized by a certain total temperature drop and a special value of c, he will take from the curve the voltage drop, corresponding to the temperature drop in question, and multiply this voltage drop by the correction factor $\sqrt{\frac{1}{2}\ (1-c)}$. He will find in this way the voltage drop which should prevail in his electrode, regardless of its length, in order to avoid heat-conduction from the charge into the electrode.

By resorting now further to equation (13), he finds that this voltage drop should equal rad, and since the mean electric resistivity r of the electrode at this total temperature drop is supposed to be known and the length a has been decided upon, the most suitable current density d, with regard to the electrode, is found by a simple division.

It is possible, and even probable, that this current density does not correspond to the value, desirable on account of the process to be carried out. In such a case, of course, the original assumed working conditions of the electrode may be adjusted in order to satisfy both considerations, or some other compromise may be effected. It is also perhaps possible to select electrodes of another and more suitable material in such a case.

In one way or the other way a set of conditions may thus be worked out from calculations supported by practical experiments, which will give ultimately the best economical efficiency of the furnace electrodes with regard to the electrode losses and costs and to the process worked.

HÖGANÄS, SWEDEN, September, 1909.

Cyanidation of Manganese-Silver Ores.

Some of the metallurgical difficulties which have been encountered in the cyanidation of manganese-silver ores in Mexico are brought out in two communications by Mr. ROBERT LINTON (of Los Angeles, Cal.) and Mr. E. M. HAMILTON (the well-known metallurgist of the Butters interests) to the *Journal of the Chemical, Metallurgical and Mining Society of South Africa.* They are published in the issues of March and August, 1909, respectively.

The problem with this special class ore is to unlock the silver in the manganiferous ore so as to make it soluble in potassium cyanide solutions. The insoluble silver is contained principally in the highly oxidized surface ore between the croppings and the 200 level, while ore from the bottom of the mine usually yields 90 to 95 per cent of the silver without any trouble.

Mr. ROBERT LINTON found a solution of the problem in preliminary chloridizing the ore. By treating with potassium chlorate and hydrochloric acid, or roasting with salt and sulphur, and following this treatment by weak KCy solutions in the usual manner, a uniformly high rate of extraction was obtained.

For operation on a practical scale Mr. Linton proposes to apply the common laboratory method of preparing chlorine, using salt, manganese dioxide and sulphuric acid according to the reaction:

$$2NaCl + MnO_2 + 3H_2SO_4 = MnSO_4 + 2HNaSO_4 + 2H_2O + Cl_2.$$

The salt was mixed with the ore, crushed through 100-mesh screen. The sulphuric acid was added in weak solution (5% H_2SO_4) and allowed to stand with occasional agitation for 24 hours. The solution was then filtered off, the residues washed and treated with 0.2 per cent KCy solution. The silver extraction varied from 60 per cent to 94 per cent. The method has the advantage of low cost of materials; commercial sulphuric acid and salt are cheap, and the manganese dioxide is already present in the ore. So far the method has been applied by Mr. Linton on a laboratory scale only.

Mr. E. M. HAMILTON, in his quite extended experiments with manganese-silver ore, has reached somewhat different conclusions. He confirms the difficulty of dissolving the silver. He tried cyanidation with all strengths of cyanide, even up to 5 per cent, on samples of the ore ground to pass 200 screen, and could only extract from 5 per cent to 15 per cent of the silver. He tried the addition of all kinds of reagents, such as lead salts, oxidizers, chlorides, oxygenation with air, hot solutions, etc., without effect.

Since the difficult ore is from the highly oxidized rock, while the ore from the bottom of the mine offered no difficulties, Mr. Hamilton concluded to treat the difficult ore first with a reducing agent. He accordingly subjected the finely ground ore to treatment with solutions of various reducing agents, among which were hydrogen sulphide, sodium sulphide, sodium hydrosulphide, and roasting with sulphur in a closed vessel. The charges were agitated for about 24 hours, and then well washed with water and cyanided by agitation in bottles.

The sodium sulphide had no effect whatever, but both the ammonium and sodium hydro-sulphides and the hydrogen sulphide increased the subsequent silver extraction to about 73 per cent against about 5 per cent by straight cyaniding. The cyanide consumption was also increased from about ½ lb. per ton in straight cyaniding to 12 lb. per ton for the samples treated by hydro-sulphide and to 27 lb. for that treated by hydrogen sulphide. The resultant cyanide solutions carried large quantities of thiocyanate.

The samples roasted with sulphur have about the same yield as those treated with hydro-sulphide, and about the same cyanide consumption.

To try to reduce this heavy loss of cyanide, the ore, after reduction treatment, was given various treatments before cyanidization, among which were the application of chlorine water and various chlorides and of oxidizers, such as potassium permanganate and hydrogen peroxide, and also the blowing of air through the

pulp; they were then well washed before cyanidation. In the case of intermediate oxidation tests some cyanide was saved in the subsequent treatment, but the extraction of silver was considerably less than when the ore was cyanided immediately after the reduction treatment. The intermediate chlorine treatment made no difference in the cyanide consumption, but increased the silver extraction by 3 per cent or 4 per cent.

Owing to the excessive cyanide consumption and the low value of the ore ($8.00 to $10.00 per ton) this method of treatment by reducing agents could not be entertained, although if the cyanide loss had been normal the method would have been well worth considering. The reason why this treatment increased the silver extraction was rather mysterious, and attempts were then made to ascertain the mode of occurrence of the silver.

By grinding the ore to pass 200 screen and boiling for an hour in strong nitric acid, then washing well with distilled water and assaying the residue, the latter was still found to contain 75 per cent of the original silver content. This residual silver insoluble in nitric acid could not have been in the metallic or sulphuric forms, nor was it mechanically inaccessible in the ordinary sense, because a sample of the pure clay slime from the ore was even more refractory to nitric acid than the general sample. It might have been in haloid form, but in that event it should have been soluble in cyanide or sodium thiosulphate, which reagents had practically no effect on it.

About this stage of the inquiry Mr. Hamilton obtained the assistance of Mr. G. H. Clevenger, who made many experiments, of which the following is a short summary: (1) Bromocyanide, results rather inferior to those by straight treatment. (2) Addition of zinc dust as a reducing agent, no result. (3) Addition of metallic sulphides with a view to breaking up any hypothetical haloid compounds, no result. (4) Addition of strong alkali with and preliminary to cyanide treatment, no result. (5) Preliminary treatment by pan amalgamation, no result. (6) Preliminary treatment with chlorine and bromine prior to cyaniding, no result. (7) Preliminary roast before cyaniding, result—not a trace of silver soluble in cyanide. (8) Preliminary chloridizing roast, result—fair silver extraction (75%). (9) Concentration of the ore ground to 200 mesh, result—tailing assayed rather higher than concentrate. (10) Oil concentration, no result. (11) Acid flotation, no result. (12) Preliminary treatment with hydrosulphides, results confirmed the tests made by Mr. Hamilton as described above. (13) Preliminary treatment with hydrochloric acid, result—94 per cent extraction of the silver.

From the foregoing it appeared that the silver is in very intimate association with some other mineral, probably with the manganese, possibly occurring as a definite manganese-silver compound.

As to how the silver may be made amenable to cyanide solution, however, Mr. Hamilton concludes that chloridizing is not the only, and probably not even the best, method. He is led to think that instead of trying to attack the silver, which is comparatively small in quantity, the aim should be to attack the predominant partner in the combination—that is, the manganese.

In the above detailed tests a chloridizing roast yielded only 75 per cent of the silver on subsequent cyanidation, while the preliminary treatment with hydrochloric acid allowed an extraction of 94 per cent. Of course, in this latter instance it may be assumed that the result was due to nascent chlorine formed by the manganese dioxide; it might, however, be equally well assumed to be due to the dissolving action on the manganese, exposing the contained silver to the action of the subsequent solvent, and this view would seem to be strengthened by the fact that the chloridizing roast gives results so much inferior to those of hydrochloric acid.

But if this latter view be correct, how are we to account for the results due to a preliminary reduction with hydro-sulphide? The only suggestion Mr. Hamilton has to offer is that the manganese, being converted into sulphide, became sufficiently soluble in the cyanide solution to expose most of the silver to the action of the solvent, forming thiocyanate and mangano-cyanide of potassium.

Working on the hypothesis of the necessity of finding some solvent that would break up the combination and free the silver, he tried a preliminary treatment with many reagents. (1) Nitric acid had been found useless in the early stages of the investigation, probably because it did not attack the manganese dioxide. (2) Hydrochloric acid, while very effectual, appeared to be prohibitive in cost. (3) Sulphuric acid was without effect. (4) The hydro-sulphide treatment, while being effectual, was prohibitive on account of the loss of cyanide, though he found it possible to regenerate KCN from KCNS by electrolysis with caustic soda, and it might have been possible to recover some of the cyanide in this way. (5) Finally he tried 5 per cent solution of sulphurous acid. After washing and cyaniding the residue he obtained an extraction of 84 per cent of the silver with a cyanide consumption of only 4 lb. per ton of ore. This method seemed by far the most feasible of any, and if the ore had assayed a few dollars higher than it did, the method would certainly have been tested on a working scale. The amount of sulphur required would in this instance have been about 100 lb. per ton of ore, which was more expense than the grade of rock would have warranted.

Thus Mr. Hamilton concludes from the foregoing results that there are several methods of treatment besides chloridising which were found to give good cyanidizing extractions on the silver in this manganiferous ore: (a) Preliminary roasting with sulphur in absence of air. (b) Preliminary treatment with alkaline sulphides. (c) Preliminary treatment with hydrochloric acid (which may be considered to fall under the chloridizing class). (d) Preliminary treatment with sulphurous acid.

Of all these the last seems to Mr. Hamilton the most practicable and least expensive, and with an ore assaying a little higher than that which was experimented on, would seem to offer a workable solution of the difficulty in the cyanidation of these manganese-silver ores. It may be remarked that the gold in such ores usually yields a uniformly high extraction of about 90 per cent under almost any circumstances, regardless of the behaviour of the silver.

Why Is Electro-Steel Sometimes Unhomogeneous?

By Assar Grönwall.

Several steel manufacturers in England, Germany, and the United States have found that electrically produced steel is at times unhomogeneous. In one and the same ingot the one end may be of high quality, while the other end is quite inferior. This complaint has been made too often to accept the usual explanation that in the beginning of electric steel manufacture part of the steel which was placed on the market was not yet up to perfection, and that ever since the conservative crucible-steel manufacturers, unwilling to abandon their crucible furnaces, emphasized on all occasions the lack of homogeneity of electric steel.

The main part of the high-class steel hitherto produced in the electric furnace has been made from cold raw materials, viz., pig iron and scrap. The furnaces used have principally been of the following three types: First, single phase electrode furnace with two adjustable electrodes (Heroult). Second, single phase electrode furnace with one adjustable electrode and one bottom electrode (Girod). Third, induction furnace.

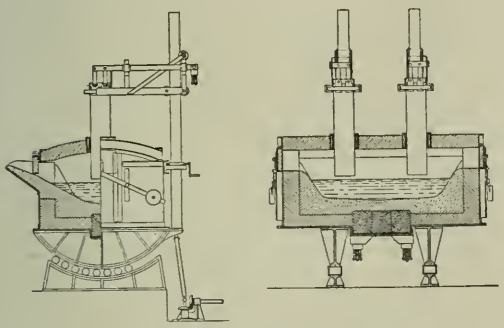
An investigation of the principles of operation of the different systems will give an explanation why lack of homogeneity is sometimes found in the steel. As to the Heroult furnace, after the main part of the charge has been molten the current passes from one electrode through an arc to the slag, then through the slag and the upper part of the metal, and through another arc back to the second electrode. The main part of the heat is produced in the two arcs, a smaller part in the slag, and only a very small part in the metal. Thus the metal is heated

through conduction from the slag, and may therefore not be uniformly heated; the surface is always hotter than the metal near the bottom, as the hotter metal is lighter than the cooler.

Therefore it may happen that if, for instance, a large piece of scrap has been thrown in the furnace with or after the other charge, or if such a piece has come to be lodged in a corner of the smelting chamber, this piece may be barely molten when the charge seems to be ready for tapping, to judge by the look of the slag or from the tests. If, then, the metal is tapped, the hottest and purest steel will run out at first, and the cooler unrefined metal at last.

In steel furnaces with one adjustable electrode and a bottom contact, just the same can happen; however, this type is in this respect more advantageous, since some part of the heat here is developed in the bottom.

In the induction furnace the same conditions may also exist. In it the electrical energy is converted into heat in the bath itself. If the lining is properly made, the cross-section of the bath is the same all over the annular hearth, and the development of heat is uniformly distributed. But if, for instance, after some time the lining in some place is eaten away and thus the cross-section enlarged, less heat is developed just at that



SWEDISH ELECTRIC STEEL FURNACE.

place where rather more heat is wanted, since more metal is accumulated there. This unequal temperature at different parts of the bath may, of course, lead to non-homogeneity of the steel.

A new type of electric steel furnace recently patented and placed on the market by the Swedish Elektrometall Company seems to fulfill better the conditions for getting a homogeneous steel. This furnace is shown in the adjoining illustration. The electrical energy is supplied in form of two-phase currents, one of the terminals of each of the two phases being connected to the two adjustable electrodes, while the two other terminals are both connected to the bottom contact. The two-phase currents produce a rotating magnetic field in the bath, which causes a circulation of the metal sufficient to get a homogeneous product and a uniform temperature in all parts of the bath. Since the circulation takes place here in a vertical plane, the metal near the bottom is continuously brought up to the surface and the hot slag.

In all the above types of furnace it is important, when producing high-class steel, that the time for treating one charge is sufficiently long. A prolonged treatment also makes sure that the metal is completely freed from gases and slag. This is of great importance for the quality of the steel, although it is as yet impossible to prove the presence of gases by analysis.

It is, of course, necessary to tap all the steel into a ladle before tapping into the moulds in order to get the metal thoroughly mixed. The author has seen at one steel works that the steel was tapped from the furnace (an induction furnace) into a small ladle, taking only a quarter of the charge, so as to run metal into the moulds, placed on a rotating table, simultaneously with the tapping from the furnace. Since the metal could not possibly be well mixed, this procedure is not recommendable.

Finally, it is to be added that the production of high-class steel always requires the greatest accuracy as well as long experience, and the production of electric high-class steel is by no means an exception from this rule. The attendance of an open-hearth furnace is never left to a person with less than one year's experience, and it is not to be expected that it is otherwise when dealing with an electric furnace. The electric furnace has been in practical use for too short a time. There are to-day not yet many men thoroughly familiar with the running of an electric steel furnace for high-class steel. But after some years' experience the electric furnace will displace the crucible furnaces, which are too uneconomical.

Calculations for Dryer Design*

BY DR. WILLIAM M. GROSVENOR.

The following methods were developed as a matter of commercial necessity. They were needed to design a great number of drying installations adapted to meet widely different requirements, operating under a system the advantages of which have hitherto been largely overlooked, i. e., the repeated circulation of the same air over condensing coils to remove moisture, over heating pipes to increase the "moisture capacity," over the material being dried and again over the condenser.

Surprising steam economies are thus accomplished, in some cases amounting to more than 80 per cent. Insurance risks are reduced. So-called "moist drying" becomes a matter of course, great capacity is permitted, and complete independence of climatic conditions makes accurate design and perfect regulation possible.

The engineering of drying is to-day one of the most neglected and by no means one of the most simple branches of applied science. There are thousands of installations where the air travels 10 feet in idleness to one of useful occupation, where it is taken from the streets and the gutters and blown loaded with bacteria over fermentive products (many of them food stuffs), where it is received ice-cold and heated up 50° or 100° before it begins to do its profitable work, or is drawn in nearly saturated at 85° to dry a product that cannot safely be heated above 95°, where, worst of all, it is expected to reverse the performance of the widow's oil jug, and to keep on drinking up moisture indefinitely without renewal or dehydration. Taking advantage of the variable weather conditions, which the seller of machinery had no object in controlling, the machinery was made big enough—the bigger the better.

In developing simple, rapid, and at the same time reasonably accurate methods of design, we were met at once with the fundamental difficulty that there is no simple equation expressing the relation between the tension of aqueous vapor and the amount of water, either by volume or weight, saturating air under given conditions.

The next difficulty was that the base or divisor (cubic foot) of all humidity calculations has hitherto been most unfortunately selected, as it varies with every change of pressure, temperature, or humidity, needlessly complicating all calculations. Lastly, that "percentage humidity," more properly called "degree of humidity," is not really comparable percentage at all. Ten per cent of humidity means that 1 cu. ft. of mixture contains one-tenth the amount of water which a cubic foot of another mixture containing less air would carry if saturated under the same conditions of temperature and pressure.

While such a standard of humidity may be satisfactory for meteorological records, practical design in a field thus obstructed was a dangerous thing to turn over to subordinates, and it seemed advisable to begin by getting rid of stumpage and doing some grading. Finally there was marked disagreement in published tables of the essential constants.

The last question was first taken up. The original sources were examined and an entirely new set of calculations made

*An abstract of a paper presented at the Pittsburg meeting of the American Institute of Chemical Engineers. The complete paper is published in Vol. I. of the Transactions of the American Institute of Chemical Engineers.

from vapor tensions to weight of water per cubic foot, using the following formulæ and constants:

Density of air + .04% CO_2 = $\frac{1.293052}{1 + .00367 \times \text{Temp. C.}}$ in kg per cu. m.

Density of water vapor = 62186 × density air.

Ratio of density at partial pressure to density at 760 mm = 1/760 × partial pressure in mm.

Wt. in kg of 1 cu. m of residual air = 1/760 × part. press. × density of air (in kg per cu. m).

Wt. in kg of 1 cu. m of water vapor at part. pressure = 1/760 × 0.62186 part. pressure × density of air.

Specific heat water vapor = .475

Specific heat of air = .2373.

TABLE I. HUMIDITY TABLE.

Kg per cu. meter × .062428 = lb. per cu. ft.

Results of these calculations are given for every degree Fahrenheit in Table I (Humidity Table).

These results (Col. 3, Table I) differed by as much as 4 per cent from the various published figures, but showed a surprising agreement (¼ per cent due to allowance or 0.04 per cent CO_2) with the figures of the United States Weather Bureau. The reason for this was inquired into. Quoting from the Psychrometric Tables of the United States Weather Bureau of 1900 (prepared by Dr. C. F. Marvin, Professor of Meteorology), it will be seen how carefully the Weather Bureau's tables were prepared:

"The vapor pressures employed were derived from Broch's reduction of Regnault's observations. All the values given by these tables at temperatures below the freezing point are noticeably higher than Regnault's observations. In view of this systematic discordance and the further circumstance that Regnault's experiments did not include observations at the extremely low temperatures frequently recorded at Weather Bureau stations, the writer (Dr. Marvin), in 1891, made a new determination of the maximum pressure of aqueous vapor at low temperatures.

"In the course of these experiments it was found an easy matter to reduce the temperature of the water employed many degrees below 32° Fahr., without freezing it, and in these cases the vapor pressure was higher than the pressure from ice at the same temperature. Independent experiments in Sweden, by Julius Johlin, at about this time, led to the same results.

"A comparison of the vapor pressures derived from the several sources mentioned shows that Broch's computed values at low temperatures do not agree at all well with Regnault's experiments, from which they are derived, whereas the experimental results of Regnault, Johlin, and the writer (Dr. Marvin), agree very closely.

"At temperatures below 32° Fahr., therefore, it has been considered necessary to reject Broch's values, and the vapor pressures over ice, as deduced from the writer's experiments, have been used in the calculation of the tables. At temperatures above 32° Fahr. the values taken from Broch's tables are employed. At 32° Fahr. the value for the vapor pressure found by the writer from the mean of a large number of experiments was identical with that of Broch; hence, there is no break in the continuity of the two tables at the point of junction."

The calculated weight of water per pound of air does not agree with actual determinations, but shows progressive differences, possibly owing to association of molecules in the vapor, which are too small in magnitude, however, to affect our present purpose.

Regarding this difference Dr. Marvin writes:

"In all ordinary circumstances it is assumed that the expansion and contraction of partially saturated aqueous vapor is in accordance with the same laws as apply to air and ordinary gases, which do not easily condense to the liquid state.

"The adopted density of saturated aqueous vapor is not determined directly from experiment, but is deduced theoretically from the observed fact that two volumes of hydrogen and one of oxygen combine to produce two volumes of water vapor.

"The weights of unit volumes of hydrogen, oxygen, and dry air are accurately known, from which the specific gravity of aqueous vapor is found to be 0.6221."

The compared figures from various sources were submitted to Dr. Marvin, but he replied that, "The Weather Bureau has not attempted to measure the quantity desired directly; in fact, the difficulty of experimentally maintaining a condition of absolute saturation and avoiding supersaturation, or mechanically suspended moisture on the one hand and superheating on the other, is so great as to perhaps render the results thus obtained less acceptable than the theoretical values."

We must, therefore, accept these figures as generally recognized throughout the United States and at least as well established as our purpose requires.

New Definitions of Humidity, etc.

In the next place a graphic method of calculation was desired, for rapidity and freedom from gross error, much more dangerous than slight inaccuracy. Also it was sought to visualize as far as possible what actually occurred to simplify comparison. A number of trials proved it far more satisfactory to disregard entirely the question of volume until it finally became necessary to calculate cross-sections of air ducts, passages, etc.

A great gain was made by regarding "humidity" as "the pounds of water carried by 1 lb. of air (or equivalent weight of other gas having the same volume) when saturated at a given temperature and pressure," and regarding the "percentage humidity" as "the weight of water actually carried by a pound of air divided by the maximum which could be carried by that pound of air under the same conditions."

This suggested as a substitute for specific heat something which we called the "humid heat," namely, "the b.t.u. required to raise 1° Fahr. 1 lb. of air, plus whatever water vapor it might carry when saturated at the temperature and pressure," and a "percentage humid heat" varying regularly with the "percentage humidity" between that of air alone and that of the saturated mixture corresponding to the same conditions.

Similarly we obtained a new "humid volume," i. e., the volume of 1 lb. of air when saturated under known conditions, and a corresponding "percentage humid volume" varying with the percentage of saturation between the specific volume of 1 lb. of dry air and the volume of 1 lb. of air saturated under the same conditions. We use the usual "density" plotted as shown and a "percentage density" (which does not vary proportionally with percentage humidity) only for calculating velocities in $V = k\sqrt{h\frac{d-d}{D}}$, for gravity circulation plants where k is always uncertain and damper regulation can be provided.

It has been simply delightful to find the ease and facility with which calculations could be carried out when dealing with conditions thus defined.

Given a mixture (let us say saturated 90°), all we need to do for the heat capacity is to pass horizontally across to the "humid heat" curve (see chart I accompanying this issue as a supplement) and if we want the heat capacity of any unsaturated mixture, we find the corresponding temperature and percentage of saturation, dropping vertically downward (merely a change in temperature) until we reach the saturation curve and then horizontally across to the heat capacity of this saturated mixture. If we want the volume or density of any saturated mixture it is directly given by horizontally crossing to the "humid volume" or "density" curves.

One difficulty (not yet overcome in any other way so far as the writer has been able to learn) is presented by the question: "How much moisture will a saturated (or unsaturated) mixture, which has been heated to a certain temperature and is used for the drying of any material, take up before it becomes saturated (or 90 per cent or 80 per cent saturated, if we prefer) and to what temperature will it fall?" It is necessary, at present, to assume the specific heat of water vapor as constant,[1] 0.475, though there is both theoretical and experimental evidence that under these conditions it acts as superheated steam with a variable specific heat.

But assuming it constant, the law of cooling is obviously

$$\frac{dx}{dt} = \frac{1.438\,S}{1601 - t}$$

in which x represents the weight of water per pound of air, t represents the temperature (Fahrenheit) at which evaporation is stopped, and S the specific heat of the mixture which we are heating and which is to be cooled by the evaporation it causes. But we have not any similar equation to express the line of saturation, 90 per cent saturation or any other degree, and we cannot solve our problem mathematically. The latest German

[1] "Specific Heat and Total Heat of Superheated Steam," Geo. A. Orrok, "Power," Aug. '04, p. 426.

works on this subject give us nothing but a clumsy method of interpolation which requires a preliminary calculation of cumbersome tables and repeated trial calculations to select values which will approximately satisfy the two requirements.

We can, however, represent the direction of this "cooling by evaporation" graphically by the "lines of cooling." It is apparent that no matter what the maximum temperature may be, if the condition of our preliminary mixture is represented by a point on any one of the curves of percentage saturation, the action of heating it is fully portrayed by elevating that point directly upward to the line of maximum temperature (neither its specific heat nor "humid heat" is changed).

The direction of its fall in cooling dx/dt will be the same no matter whether saturated at 75°, or 50 per cent at 96°, dependent upon its original air and water components expressed by the distance from the axis of Y (as governed by the numerator $1.148S$) and upon the temperature where it finally ends up in the course of its cooling (as governed by the denominator $1601-t$). In considering the cycle it is perfectly correct to assume all the evaporation to have taken place at this final temperature.

We have, therefore, drawn for various final temperatures on our diagram a series of straight diagonal lines on the same Humidity Curve Sheet representing dx/dt for various initial mixtures, the water content of which is given by the distance from the Y axis where the left-hand end of each line ceases. On the left-hand side of the curve, owing to the slight difference of inclination of corresponding lines for successive final temperatures, it is necessary to draw only one of these fan-shaped sets of lines and these need have been drawn only for each successive 10° of temperature.

Here the saturation curves show that the temperature varies rapidly and water content (with corresponding specific heat) varies slowly. On the right-hand portion of the curve, where the variation of "water absorbed" (and of specific heat) is greater, they are needed every 5°.

The lines for intermediate points can be drawn if desired, but it will be noted that a difference of 5 produces a difference of value of $dx\ dt$ of about ½ of 1 per cent.

Now, it is apparent that with these lines upon our curve we may take any given mixture which is to be heated (whether saturated or not to start with), run up the vertical to the maximum allowable temperature and selecting from the nearest group of lines of cooling that one which starts from the nearest position with reference to the Y axis, we may follow down parallel to this to the saturation curve.

If we are not considering the complete saturation, but only the 70 per cent saturation of the final exit mixture (before cooling and condensation) this is only a first approximation. Upon noting at what temperature the diagonal intersects the curve of 70 per cent saturation we must then redraw our incline, parallel to the incline corresponding to this mixture for this nearest final to the one thus discovered.

Example Showing Use of Curves.

As an illustration of the use of these curves, assume 50 lb. per minute of water to be removed at a temperature not exceeding 110° Fahr. with available air at 80° Fahr. and 90 per cent saturated. Assume the material to be so distributed and exposed that the air will leave the dry room at 80 per cent saturation. How much air will be required? What will be its final temperature, etc?

On the chart we find 80° Fahr. ordinate crosses the 80 per cent humidity dotted curve at an abscissa of 0.0200 lb. water per pound of air. If heated to 110° the change of condition is represented by increased ordinate with no change of abscissa (moisture content), the point rising vertically to 110°, where we find it between 50 per cent and 60 per cent humidity curves, or approximately 54 per cent saturated.

On exposure to the material being dried, the air will cool and take up moisture, changing its condition parallel to the inclined straight line to the immediate right of the point, 0.0200 lb. 110°.

This diagonal shows that it will be 50 per cent saturated at 101°, 70 per cent saturated at 96°, and 80 per cent saturated at 90°, with an abscissa of 0.0248 lb. water per pound of air, having picked up $0.0248 - 0.0200 = 0.0048$ lb. water per pound of air.

To remove 50 lb. water per minute would require $50 \div 0.0048$, or about 10,000 lb. of air per minute. To ascertain the heat required for this entering air we require the heat capacity of air at 80°, 90 per cent saturated.

Starting from the same point as before, we drop to the 100 per cent saturation curve, and find that our mixture has cooled to 77¼° Fahr., and passing on the horizontal of 77¼° toward the left, to the Humid Heat curve, we find that each pound of air requires 0.248 b.t.u. per degree Fahrenheit to heat it and its water of saturation. We have then $0.248 \times (110 - 85°) \times 10{,}000 = 62{,}000$ b.t.u. per minute.

To find the volume of 10,000 lb. of air, let us say at the exit, where each pound is carrying 0.0248 lb. of water with it and is 80 per cent saturated, we have only to pass across from the point 80 per cent, 0.0248 lb., 90° Fahr. (where we ended the first operation), along the horizontal of 90° to the Specific Volume and the Humid Volume curves. The specific volume of dry air at 90° is 13.86, that of saturated air (Humid Volume) 14.55, and 80 per cent of this difference is $0.69 \times 0.8 = 0.552$ added to the volume of dry air $= 13.86 + 0.55$, or 14.41 cu. ft. per pound $= 144{,}410$ cu. ft. air per minute at the exit.

The lines at present shown upon the sheet have amply sufficed for all purposes of practical design and have made it possible almost at a glance to select the conditions best suited to a given problem. They show vividly, for instance, the great advantage secured by applying heat between successive partial saturations by progressive exposure to the material being dried —also the enormous economy of restricted ranges of temperature.

Finally, we are developing therefrom, with little labor or calculation, a series of curves showing for every 10° Fahr. entrance temperature, the maximum conditions of efficiency, assuming various saturations of air before and after passing over the material, and a locus of maximum efficiency for these entrance and exit assumptions.

Heat Losses from Pipes.

The auxiliary curves (see chart II. Loss of Heat from Pipes, accompanying this issue as a supplement) are intended to simplify calculations of heating pipes and present a graphic solution of the law of Dulong and Petit, as modified by Peclet and Box. The use of the curves is extremely simple and is shown by arrows. They enable us to obtain the two components, radiation and convection loss, from pipes ⅛ in. to 12 in. U. S. standard size, per foot of length singly or in any of the 10 positions which they may occupy in a bank.

The fundamental basis of these calculations (0.64 b.t.u. radiation and 0.05 b.t.u. convection) are not accurate by several per cent, and cannot remain constant, as the pipes rust or gather dust. No effort, therefore, has been made to secure greater accuracy than given in the figures of Box. A safety factor has been added to the result given by the curves and the size of this factor is being gradually reduced by experience.

In our designs hitherto, the velocities of gases across the heating pipes has always been practically that due to natural circulation, and no provision is shown here for variable velocities. It can easily be added by a single inclined line if desired.

(The original paper of Dr. Grosvenor contains here several tables of figures representing the derivation of the curves of Chart III. These tables are here omitted, since the results are given completely on Chart II.)

The losses by convection for each standard size pipes are plotted with temperature difference as ordinates and b.t.u. per hour as abscissæ in the lower half of the curves of Chart II.

The presentation of radiation is somewhat complicated by the fact that the correction factors vary both with temperature and with difference of temperature. These correction factors are represented by the fan-shaped set of curves on the upper half of the diagram.

It is frequently desired to use pipes in banks wherein position greatly affects radiation, though not influencing convection. Modified factors reduced in proportion to the radiating angle obscured by the other pipes of the bank are, therefore, calculated (assuming Crane's Standard malleable return bends are used for assembling) for the various possible positions indicated by Nos. 1 to 10 on the diagram accompanying the chart. These various factors for the isolated and for the various partly obscured positions are given on the chart. The point to which the diagonal for this graphic multiplication should be drawn is indicated on the main guide line, but only a few of the diagonals to these points have been drawn, as our own particular interest centers mainly on combinations of 1-in. pipe. The other lines can easily be drawn when required.

The simplified calculation of wall, ceiling and window losses was found to be well worked out in curves drawn by Mr. Burt S. Harrison and published in the *Heating and Ventilating Magazine* of November, 1907.

Similarly the capacity and drop in pressure in steam mains has been carefully worked out by E. C. Sickles and published in *Power*.

The design of the condenser remains for consideration. It is a surprising fact, but a most thorough search has revealed no data applicable to this case. We use banks of horizontal 1-in. pipe with water or brine circulating within them. If they were merely cooling air we could find ample data for design. They would transmit about 1.5 b.t.u. per square foot per degree per hour. If they were condensing practically pure steam, some quite recent work would be available. They would transmit from 150 to 300 b.t.u. per square foot per hour. But they do neither and yet they do both. A formula has been developed upon purely theoretical grounds similar to those of the law of mass action. It will be submitted later (not as a solution, but as a view for criticism and test), together with examples showing how far it is justified by actual practice.

Notes on Electrochemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

Societies and Institutions.

The Faraday Society has delayed its opening meeting of the season until November 30th, and the Physical Society's annual exhibition of apparatus has also been fixed for a later date than usual, the 14th of December. The inaugural address of Dr. Gisbert Kapp, president of the Institution of Electrical Engineers, dealt with generators, transformers, power transmission and electric railways, but did not touch on any metallurgical subject. His remarks as to the necessity of educating the potential users of electrical plants are worthy of consideration; but many will share the view expressed in a recent article in the *Times* that "it is to be regretted that Dr. Kapp, instead of covering such an extensive field in his survey, did not devote his address almost exclusively to the enormous benefits to be obtained through the more rapid application of electricity to textile and other factory purposes."

The Reduction of Some Refractory Metals from Their Chlorides.

In a paper recently presented to the Chemical Society by Messrs. J. Norman Pring and W. Fielding, the authors have described their investigations of the reactions by which certain refractory metals may be prepared by the action of electrically heated carbon rods or filaments on their volatile chlorides. When tungsten chloride was used without admixture, under diminished pressure, decomposition occurred at temperatures between 1200° and 1500°; and with molybdenum chloride, below 1300°, adherent deposits of the pure metals being formed on the carbon. At higher temperatures carbides were produced; but when small amounts of aqueous vapor were present the metals were reduced free from carbide. Pure crystalline silicon was obtained at temperatures between 1700° and 1850° by addition of hydrogen to the vaporous chloride. At first a thin layer of carbide was formed; and this prevented carbonization of the subsequent deposit until the temperature was raised to 1900°, when carbide alone was formed. In the case of boron, the carbide B_6C, was always deposited at temperatures between 1800° and 2000°. Approximate photometric determinations of the radiating power of the metal-coated carbon showed a very great increase in luminosity for a fixed consumption of power, amounting with tungsten and molybdenum to nearly three times the radiation from carbon rods. Deposits of silicon and of boron carbide caused only a very slight increase.

A New Use for Electrolytic Hypochlorite.

Dr. F. W. Alexander, medical officer of health for Poplar, has been carrying out a series of experiments on the purification of the water in the borough swimming baths by the addition of electrolytic disinfecting fluid. The large first-class swimming bath has a capacity of 75,000 gallons, and it was found that the addition of 100 gallons of electrolytic hypochlorite solution in four installments—40 gallons on the Saturday, 40 gallons on the following Monday, 10 on Tuesday night and 10 on the Wednesday—had the effect of rendering the water perfectly clear and fit for use, whereas the bath is usually emptied and cleaned on Tuesday and fresh water run in. After a total of 899 persons had used the bath on Wednesday the water became slightly clouded, but the bottom of the bath was distinctly visible. On the Thursday night after 1159 persons had used the bath the water was discolored and the bottom somewhat obscured. The superintendent reported that the effect of the addition of the electrolytic fluid was to preserve the water in as good a condition after five days' use as it would have kept in one day's use only without such addition; and the secretary of a swimming club stated that the members felt fresher, not languid, and that they had lost the usual "dead feeling" on coming out of the bath.

One of the laundresses employed in cleaning the swimming costumes reported that those articles had no unpleasant odor since the fluid had been used, but previously they gave off a most unpleasant smell. The chemical and bacteriological report by a Fellow of the Institute of Chemistry on the bath water without hypochlorite shows that the chlorine present as chlorides was 2.5 grains per gallon as against 2 grains per gallon present in the East London water supplied. Some nitrites were present; the amount of oxygen required to oxidize the organic matter present was 0.1 grain per gallon, which is almost the figure given by an ordinary slightly polluted water. Qualitative tests showed the presence of B. Coli communis, Streptococci, and Staphylococci; but B. Enteritidis Sporogenes was not present. Quantitative tests showed approximately 10,000 organisms per cc. capable of growing at blood heat, and 2000 capable of growing at ordinary temperatures. The preponderance of the former indicates that they are chiefly of animal (human) origin. Samples of the water to which hypochlorite had been added were found to contain no nitrites; free chlorine estimated at 0.5 mg. per litre; and after incubation for four days no organisms were found growing in the cultures made, which result might have been anticipated from the fact that free chlorine was present.

In the course of these experiments a peculiar fact came to light, namely, that the water used by women and girls was always dirtier than that used by the same number of men and boys; and after investigation the conclusion was arrived at that this was due to dust accumulated in the women's long hair. The other baths of the Corporation were also treated with hypochlorite, and the same satisfactory results were obtained; and

the masters and mistresses who attended with the boys and girls from the schools said the water was fresher, more invigorating, and had lost its body odor. It is proposed to use about 38 gallons of electrolytic fluid to the bath of 75,000 gallons. The cost of this quantity would be about 55 cents.

For some time past the public health officials of the borough of Poplar have been using electrolytic hypochlorite instead of carbolic acid for general disinfecting purposes, and have found it combines higher efficiency with considerably reduced cost

Company Meetings.

The Castner-Kellner Alkali Company.

This company's fourteenth ordinary general meeting was held on November 25th, under the presidency of the Chairman, the Rt. Hon. G. W. Balfour, who congratulated the shareholders on the financial statement. The net profit—but without deduction for debenture interest or depreciation and reserve—was £134,154, which was an increase of more than £18,000 on last year's profit. This result was more satisfactory than appeared at first sight, because this year was by no means a prosperous one in the chemical trade, whilst the increase arose in almost every product which the Company turned out, which must be taken as indicating the broad basis of prosperity on which the company rested. Deducting debenture interest and the interim dividend paid in May, the net available balance is £117,711. On last year's accounts, as in previous years, loss was written off for realization of disused plant. In 1907 the amount was about £16,000. Usually it was a comparatively small sum, but this year it did not appear at all. Losses in respect of realized plant differ from usual depreciation, and this is partly the reason why the sum for depreciation has been raised from £30,000 to £35,000. On suspense account the sum of £1,370 had been written off, and as a consequence that account disappeared. A suspense account had been necessary because investigations were inevitable which it would not be fair to charge to revenue of a single year; but now that the general reserve fund was established it was to be hoped that the suspense account would not be revived. The general reserve fund was started last year, and it is proposed to carry £25,000 thereto, making its total amount £37,000 which is, in fact, a cash reserve, invested in good, easily realizable securities, and is available for the purpose of a suspense account or for dividends in less prosperous years. This arrangement being agreed to, there was a sufficient balance to pay a dividend of 9 per cent, making with the May interim dividend 14 per cent for the year, and leaving £15,840 to carry forward. The chemical trade seemed to be improving, and there was no reason to anticipate a worse result for the current year's accounts than the last year's had shown.

The report and accounts were received and adopted, and a vote of thanks to the Chairman closed the proceedings.

The Aluminium Corporation, Ltd

A scheme for the transfer of the assets of this company to a new company was sanctioned in the Companies' Court on November 23d by Mr. Justice Swinfen Eady. The petition stated that the company was incorporated with a capital of £500,000, of which £440,000 were in 7 per cent participating cumulative preference shares and £60,000 were in ordinary shares with a non-cumulative preference of 7 per cent, whilst 40 per cent of the remaining profits went to the preference shares and 60 per cent to the ordinary. The £1 preference shares issued were 257,205, of which 252,222 were fully paid. There was a debenture issue of £26,906, and a large unsecured debt. The company was wound up, and liquidators were appointed in 1908; and in May of that year a scheme of arrangement was sanctioned, but was not carried out through lack of money; nor was an attempt to realize the company's assets successful. The proposed scheme provides for the payment of the general creditors, and unsecured creditors for less than £10, in full; unsecured creditors for more than £10 would receive preference shares in the new company, and shareholders would get part-paid shares. There was no opposition; and the scheme was sanctioned, subject to slight amendment and the consent of shareholders to accept shares in the new company.

London, Dec., 1909.

Synopsis of Periodical Literature

Iron and Steel.

Electric Steel Furnace of Girod.—The chief interest in an illustrated article on the Girod furnace, by Professor W. Borchers, in *Stahl und Eisen*, of Nov. 10, lies perhaps in the somewhat personal remarks in which he expresses his enthusiasm concerning this type, which he considers to be "the simplest of the present commercial electrode steel furnaces." The keynote of the invention of Girod he finds in the way in which the steel bath is made a resistor, producing itself Joulean heat. Since the Girod furnace has been described and illustrated quite often in this journal (for instance, in our Vol. VII, pp. 9, 250, 323, 371, 458) and since Professor Borchers' article contains little that is new, only a few data on the new Girod electric steel works in Ugine (first described in our Vol. VII, p. 9, and of great interest, as being the first large and entirely electric steel works) may be given here, as Borchers has recently visited them. At present there are installed in these works three furnaces, each of two tons capacity, and two larger ones, each of 10 to 12 tons capacity. Castings up to 20,000 kg weight can be produced. Other electric steel furnaces of Girod are in use or in course of erection at the works of Oehler & Company, Aarau, Switzerland; John Cockerill Company, in Seraing, Belgium; Metz & Company, Stuttgart, Germany; Stahlwerk Becker, Krefeld, Germany; Gutehoffnungshütte, Oberhausen, Germany; Turnauer Stahlwerk von Schoeller, Ternitz, Austria; Danner & Company, Judenberg, Austria; Hungarian State Steel Works, Diosgyor, Hungary. (A Girod furnace is also reported to be in course of erection in a steel plant in this country.) The same article by Borchers was printed in *Metallurgie*, Nov. 8. The issue of Dec. 8 of this journal contains a letter by the Elektrostahl G. m.b.H., Lindenberg, which criticises various points in Borchers' article and endeavors to show the superiority of the Héroult furnace over the Girod furnace. The same issue contains a reply by Professor Borchers in which he states his reasons for considering the Girod furnace to be the superior one. Both letters are of a rather personal nature.

Armature Steel and Permanent-Magnet Steel.—A suggestive study of steel for the electrical industry is given by G. Mars in *Stahl und Eisen*, Oct. 27 and Nov. 10. For armatures and transformers a steel is wanted which has a high permeability and a low hysteresis loss—that is, metallurgically speaking, a steel which has a high content of ferrite and a coarse structure indicating a loose agglomeration of the molecules (so as to permit them to follow rapidly the reversals of magnetic polarity). This condition is fulfilled by a steel containing 2 to 3.5 per cent silicon and a very small amount (less than 0.1 per cent) carbon. The requirements of steel for permanent magnets are, of course, quite different. Here high remanence is chiefly desired. In carbon steels the remanence increases with increasing carbon content up to 0.97 per cent C and then decreases. The hardness increases and reached a maximum at 0.8 to 0.9 per cent C and then remains practically constant. The maximum of remanence has been found by Mme. Curie at 1.20 per cent, but the author's figure of 0.97 per cent C seems more probable. Tungsten steels are, however, far superior to carbon steels for permanent magnets. The best steel for permanent magnets at present

used contains about 0.60 per cent C. and 5 per cent tungsten. This superiority of tungsten steels over carbon steels is due to the presence of more free iron in the former with equal hardness. A tungsten steel of the stated composition gets highest remanence if the hardening temperature is 930° C. to 950° C. The paper contains interesting suggestions on the relation between metallurgical structure and magnetic properties.

Effect of Titanium on Steel.—An interesting paper on this subject is published by ED. VON MALTITZ in *Stahl und Eisen* of Oct. 13. In his introductory remarks he mentions some experiments made five years ago in a basic open-hearth furnace of the Dominion Iron & Steel Company in Sydney, Canada, where he used titaniferous iron ore (containing 40 per cent Fe and 16.8 per cent titanic acid) as an addition for the purpose of increasing the fluidity of the basic slag and improving the desulphurization. Metallic titanium did not enter thereby into the steel bath, but the fluidity of the slag was considerably increased without detriment to the furnace lining; a distinct influence on the removal of sulphur was also observed. The experiments were, however, not carried far enough to reach final conclusions. The author discusses in his article especially the use of ferro-titanium for steel refining. Since this matter has been discussed at length in an article by Mr. C. V. Slocum, in our Vol. VII, p. 128, and in another article on the results obtained with titanium-treated steel rails (Kessler's curve, etc.) in our Vol. VII, p. 498, we mention only the new points in Mr. Maltitz's article. Ferro-titanium, containing from 10 to 15 per cent Ti is preferably used. It is added after the steel has been recarburized and after ferro-maganese or ferro-silicon has been added. Care is to be taken that the ferro-titanium is not mixed with the slag. It should be dissolved in the steel bath itself for the purpose of removing oxygen and especially nitrogen, the resulting compounds passing into the slag. Reference is made to the detrimental effect of nitrogen on steel according to the work of H. Braune (our Vol. V, p. 51). Maltitz found in converter steel for rails 0.013 to 0.014 per cent nitrogen. When the same steel was treated with titanium, the nitrogen content was reduced to 0.004 or 0.005 per cent. This is a very important result, since "nitrogen should be considered to be at least as detrimental as phosphorus." Some figures from practice are given showing that a very homogeneous steel is obtained by means of treatment with titanium. In most cases an addition of ½ per cent of ferro-titanium containing 10 to 15 per cent Ti is sufficient. While this improvement of the quality of steel is important, it should be remembered that a material which cools quietly and without developing gases, tends to the formation of pipes, like crucible steel, if care is not taken to cast at a moderate heat. This precaution is, therefore, important. Steel treated with titanium cools much more slowly than ordinary steel; the reason for this is not clearly understood. But it is also a fact that articles of steel which have been treated with titanium are heated less than ordinary steel under otherwise equal conditions; for instance, cast-iron or steel rolls, which have been treated with a small amount of titanium, can be machined more quickly than ordinary steel rolls, on account of the smaller increase of temperature due to machining. As was noticed in our former articles, some remarkable results have been obtained with titanium-steel rails on difficult sections of railroads. These are reviewed at some length by Mr. Maltitz.

Oxy-Acetylene Welding of Sheet Iron.—In *Stahl und Eisen* of Nov. 17, H. RINNE reports on the results obtained in practice by the sheet-rolling mill of the Schulz Knaudt Company in Essen, who have used for many years the water-gas welding process. On account of its reliability and cheapness they continue to use this method for longitudinal cylinder seams. During the last years they have also employed oxy-acetylene welding, which has been found especially useful for repairs of leaks developed in seams produced by the water-gas process. The main advantage of oxy-acetylene welding in comparison with water-gas welding is that the former process permits to make the seam at will thicker and stornger than the iron sheet itself. Some care must be taken, however, in oxy-acetylene welding; the acetylene must be pure and must not contain dust or impurities; the dimensions of the burners must correspond to the thickness of the sheets; the additional steel to be put on to the weld must not be of inferior quality and should not be added until the edges to be welded together are thoroughly fused. Of main importance are the hammering of the weld and the annealing after the weld is completed. Finally, wherever it is possible, the two sheets should be welded together from both sides. If carefully carried out, the results obtained with oxy-acetylene welding are at least as good as with water-gas welding. That seams made by oxy-acetylene welding are very reliable was proven by hydraulic-pressure tests made with hollow receptacles. The published statement that only thin sheets (up to 8 mm with oxy-hydrogen and up to 10 mm with oxy-acetylene) can thus be welded is wrong, since the author has used oxy-acetylene welding with best success with sheets of 30 mm or more. There is no danger of oxidizing the material during the welding operation, if care is taken to use a reducing flame (an excess of acetylene or hydrogen), but this is quite easy.

Precious Metals.

Precipitation by Zinc.—In an interesting paper read before the Chemical, Metallurgical and Mining Society of South Africa (*Journal* of the Society, March, 1909), Mather Smith claims that the generally accepted principle is wrong that it is necessary to have 1 cu. ft. of zinc shavings for the precipitation of one ton of solution in 24 hours; he further claims that more zinc than is necessary is being used, that an excess of zinc is both harmful and costly, that precipitation boxes are often constructed on a wrong principle, and that a comparison of the rate of the flow of solution per cubic foot of zinc, which does not also include or consider the difference in area and number of compartments in the precipitation boxes, is misleading. He gives examples from his practice to prove that the superfluous zinc does a great deal of harm, "as it must occasion an unnecessary consumption of cyanide and charge the solutions with an excess of zinc, which in circulating through the plant will in a great measure be deposited as white precipitate at the heads of the boxes." The principle on which he recommends to construct precipitation boxes is to allow one square foot in area for the precipitation of one ton of solution in 24 hours, with a maximum height of 24 inches from the top of the zinc frames to the top of the solution, and with a maximum of five compartments in each box. In the discussion of the paper (April issue of the *Journal* of the Society), J. H. Johnson says the problem resolves itself more into a matter of time the solution is in contact with the zinc than the depth or amount of Zn required to a ton of solution. In the old-style boxes and in the boxes recommended in Smith's paper the time for which the solutions are in contact with the zinc was from 20 to 30 minutes or more, while in many cases now the solution is only in contact for a period of 6 to 8 minutes. Depth and amount of zinc shavings per ton of solution have to be increased when the time of contact decreases.

Zinc Dust Versus Zinc Shavings.—An interesting comparison of precipitation of gold from cyanide solutions by zinc shavings or by zinc dust was given by A. J. Clark in a paper before the Chemical, Metallurgical and Mining Society of South Africa (*Journal* of the Society, Jan., 1909). The comparative results were obtained in the No. 1 sand plant of the Homestake Mining Company on a working scale with solutions practically identical in composition, during 12 months of 1906 with zinc shavings and during 9 months of 1908 with zinc dust. The average strength of solution precipitated by zinc shavings was 0.03 per cent; if below this figure the solution was strengthened by addition of barren solution of 0.07 per cent strength. The average strength of solution precipitated by zinc dust was 0.0242 per cent; the minimum strength encountered and success-

fully precipitated by dust was 0.015 per cent. The principal comparative figures are as follows:

	Shavings	Dust.	Shavings by dust.
Tons precipitated	5909	5585	
Dollars received total	$1513	$1513	
Per cent precipitated	91 +	94.4	
All costs, labor and supply	$243.28	$76.93	$166.35
Gold in sands in barren solutions	$126.45	$99.41	$27.04
Value of cyanide in wasted barren solution	$709.00	$540.60	$168.40
Totals	$1,078.73	$716.94	$361.79

Telluride Gold Ore.—The metallurgy of the telluride gold ores of the Cripple Creek district in Colorado has been the subject of a report (edited by Thos. B. Crowe) of the Portland Section of the Chemical, Metallurgical & Mining Society of South Africa. It was published in the May issue of the *Journal* of the society. Besides a large tonnage of ore of exceptional richness, the Cripple Creek district yields ore which, on account of its refractory nature, is left standing in the mine stope or thrown upon the waste dump. The refractory nature of these ores is due largely to the occurrence of the gold in combination with tellurium, forming a compound ($AuAg)Te_2$. After a trial of other methods, which turned out failures, roasting followed by barrel chlorination and concentration has become the popular treatment. This method works very well as far as the extraction is concerned, and will continue to be used so long as the present grade of ore is maintained; but as the amount of low-grade ore standing in the stopes and upon the dumps becomes larger year after year, it becomes more apparent that a cheaper method of treatment must be found, the problem resolving itself into one of raw treatment at the mine, rather than transporting 50 miles by rail to the cheap fuel in the valley. With this end in view the Portland Gold Mining Company has carried on extensive experimentation.

An interesting feature of these experiments was the use of potassium persulphate, the object being to dissolve the tellurium. When potassium persulphate is alone in solution, it acts as a strong oxidizing agent. But when mixed with cyanide solutions, its oxidizing influence is greatly retarded. It then acts as a "slow oxidizer or depolarizer, thereby greatly increasing the dissolving power of cyanide solutions and when used in small proportions, 1 lb. to 10 lb. per ton of solution, it does not destroy the cyanide to any great extent." Potassium persulphate, when mixed with cyanide solution, completely dissolves the telluride of gold. Three processes, based on this principle, were tried.

(1) A preliminary treatment by an alkaline persulphate, followed by a treatment with a cyanide solution. The results were poor, since extreme amounts of persulphate must be used to obtain a good tailing.

2. A treatment by a solution containing both alkaline persulphate and potassium cyanide. The process was not found to be economical.

3. A treatment by a solution of an alkaline persulphate, an alkaline iodide, and potassium cyanide, contained in one solution. The object was to obtain the reaction $KCy + 2I = ICy + KI$ and thus produce cyanogen iodide (which is an exceedingly good solvent for the telluride of gold) and not to depend directly upon any of the ingredients other than cyanide and cyanogen iodide as solvents. In using this process, good tailings were invariably obtained, even with very weak solutions. But it was found that the solutions after leaving the ore and standing in contact with the air lost their cyanide, especially when heavy sulphide ores were treated. However, in passing through the zinc boxes, the deterioration of the cyanide is stopped, due undoubtedly to the reducing action encountered there. Alkaline persulphate may be produced economically by electrolysis of salt cake. "Potassium iodide, although an expensive chemical, would remain as such in the solution, the persulphate causing it to give up its iodide, this iodide combining with the cyanide to form cyanogen iodide, with the alkali to form an alkaline iodide or alkaline iodate, but always finally reverting back to an alkaline iodide, as any iodate formed would be reduced to iodide in the zinc box."

The report is discussed in the July issue of the *Journal* by D. J. Moir and C. H. Cropper and in the September issue by T. B. Stevens. Moir criticises some of the chemical statements in the report, while C. H. Cropper gives some notes on successful practice with telluride ores at Kalgoorlie, W. A. There is a wide difference in the solubility of the gold in telluride minerals. The ore being treated at Kalgoorlie is for the most part a sulphotelluride. In the early days of the field, when the grade of ore was high and the extractions low, it was discovered that tellurium was a factor to be reckoned with in future treatment. Bromo-cyanide enabled better extractions to be obtained, although the residues contained high values. At the present day the average grade of ore has fallen considerably; the highest may be taken at 55s, the lowest at 28s. In the constant effort to reduce the value of the residues the economic factor has prevailed, inasmuch as an extraction of 85 per cent on a refractory ore may show a better cost sheet than a 95 per cent. As to which of the two processes in vogue is the better, viz., dry crushing or wet crushing, is a matter of opinion, but the facts are that with the dry crushing and all roasting plants the residues are under 1 dwt. without the use of BrCy, while the wet crushing residues are 1½ dwt., the raw slime only being treated with BrCy. Total treatment costs, as they are to-day, range from 8s. 8d. per ton to 10s. 8d. for wet crushing, from 10s. up to 11s. 8d. per ton for dry crushing. The capital outlay on a dry crushing plant is greater than for wet crushing, but the difference would be compensated for in the lower residues obtained; greater improvements in roasting furnace design have advanced dry crushing practice. With the wet crushing plant, concentration of the mineral is employed, but there is a proportion of very fine mineral which is carried away in the slime and which is the cause of the higher values in residues.

T. B. Stevens asks whether the authors have made any comparative experiments, using bromo-cyanide instead of potassium cyanide and persulphate, and if so, whether the latter method gives a very much better extraction. The cost of the latter would be higher. The cost of chemicals for bromo-cyanide treatment at Kalgoorlie has always been one great disadvantage of an otherwise successful process. The writer's experiments with Cripple Creek ores showed that a good extraction could be obtained by bromo-cyanide treatment, fine grinding being a sine quâ non. At Kalgoorlie it is found most economical to take out the pyritic portion of the ore by concentration, and treat it separately by roasting and cyaniding; otherwise, in treating this very refractory material together with the bulk of the ore, the cost for bromine salts, to get a good extraction, is found to be excessive. With Cripple Creek ores the writer found this also to be the case, and, in the latter district, he believes that the small amount of high-grade concentrates could be more profitably shipped to the smelters instead of treating it at the mine.

Continuous Collection of Sand for Cyaniding.—A paper on an interesting new development in gold metallurgy on the Rand was presented by W. A. Caldecott before the Chemical, Metallurgical and Mining Society of South Africa and is printed in the August issue, 1909, of the *Journal* of this society. The new process is the outcome of long extended experiments, the object of which was to effect some saving in the very high capital expenditure for a modern cyanide plant. On consideration it appeared that the most likely prospect of success lay in eliminating the sand collecting vats, or rather in utilizing them for treatment purposes instead of merely as sand storages, which take the place of the old tailing dams. The upper vats of the superimposed type of sand plant were on their first introduction before the Boer war utilized as treatment vats as well as sand collectors, but the results of contamination of mill water with cyanide caused this practice to fall into disuse, and

in any case a considerable time elapsed between the filling of a vat and its charge yielding gold-bearing solution to the boxes. Hence, although it reduced cost of transfer to a minimum, this type of plant fell into disuse as being expensive, through having only one-half its capacity available for extraction purposes, and was replaced by separate blocks of collectors and leachers (with belt or truck transfer) in the ratio of 1 to 2 or 2 to 5, which is now the common practice on the Rand. On considering how to utilize sand-collecting vats for treatment purposes and to retain their advantages, including minimum ground space required, while avoiding the difficulties mentioned, the problem became essentially that of continuously removing the water and slime from the tailing pulp so as to leave the same in proper condition for cyanide treament. The solution was found in the use of conical classifiers in connection with a specially designed slowly rotating horizontal vacuum filter. The first filter of this kind, constructed by the author, was 10 ft. in external diameter and consisted of an annular launder 12 in. wide containing a filter cloth upon a grating as a false bottom. The filtering area was thus 28.3 sq. ft. The space under the filter cloth was connected by means of radial pipes to a central hollow spindle, in which a vacuum was maintained from a receiver.

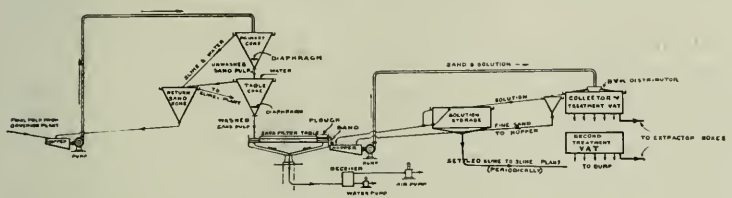

DIAGRAM OF CONTINUOUS SAND FILTRATION PROCESS.

To the lower portion of the receiver was connected a water pump and to the upper a vacuum air pump. Various other filters of the same type, but of larger capacity, have since been installed and have proven thoroughly successful in large-scale operation. Considerable details are given on the arrangement of the plant and comparative working costs. The accompanying illustration shows what is in Mr. Caldecott's opinion at present the most suitable arrangement of plant in elevation, with superimposed primary and table cones, as well as superimposed collecting and second treatment vats. The superimposed vat system under these conditions is no longer open to the objection of contaminating mill service water, while all the vats, both upper and lower, are utilized for treatment, and the cost of installing and operating transfer belts or trucks is done away with. The collecting vats used to receive the almost slime-free sand solution pulp may be of larger dimensions than usual, as settlement of slime in layers is not to be apprehended, and fewer larger units thus employed in place of more smaller ones. For the same reason the bulk of the lime used may be crushed with the ore in the battery, thus reducing the separate grinding of lime in a ball-mill or other machine to occasional periods when unusually acid ore is being delivered to the battery. Naturally the use of sand filters greatly increases the capacity of existing plants whether of superimposed or other type, by converting all the collectors into treatment vats. "The advantages which sand filters present are considerable saving in capital expenditure both for sand vats and for belt or truck transfer installation, slightly better extraction than the ordinary system unless prolonged treatment is given, a saving with superimposed vats of belt or truck transfer cost, and more slime to be treated as such at, say, 6d. per ton less than sand in vats of slightly increased diameter."

Copper.

Calculation of Blast Furnace Charges.—In the *Mining and Scientific Press* of Nov. 13, PERCY E. BARBOUR emphasizes the advantages of calculating blast-furnace charges. He describes two methods; in the first, the slag desired is assumed and the charge is calculated; in the second, the charge is assumed and the slag is calculated. The first example is based on the practice of the U. S. Smelter in Salt Lake Valley, which treats its own ores (dry and sulphide ores) together with purchased custom ores. The furnaces are 42 in. by 180 in. at the tuyeres. The conditions at the smelter require on the charge 300 lb. of ore "A," 1200 lb. of ore "B," 500 lb. of ore "C" and 300 lb. of converter slag, "D." (The assays for silica, iron, lime, sulphur and copper are given in the article.) In choosing a slag to be made, it is not the practice at this plant to make an exact singulo-silicate ($2RO \cdot SiO_2$) or other exact class slag, but to make that slag which experience has demonstrated is best suited to local conditions. This experience-dictated slag, however, approaches a singulo-silicate. Lang, in his "Matte-Smelting," considers the best slag to be generally a bisilicate of lime ($CaO \cdot SiO_2$) and a singulo-silicate of iron ($2FeO \cdot SiO_2$) in equal parts. The assumed slag in the present case is 44 SiO_2: 25 FeO = Fe 19.5; CaO 0.23. The problem is to determine the quantity of dry (silicious) ore containing high gold and silver content, and 2 per cent copper, which can be put on the charge, and the amount of lime necessary to be added. The assays of these two materials are known, and are entered on the charge-sheet. Let the required amount of silicious ore be represented by x and the amount of lime by y. The total silica on the charge is that in ores A, B, C, D (which in this case is 765 lb.), plus 69 per cent of the weight of the silicious ore, x, plus 3 per cent of the weight of the lime-rock, y; 69 and 3 being respectively the silica content of the silicious ore and the lime-rock. Therefore, the total SiO_2 on the charge is SiO_2 in pounds $= 765 + 0.69\,x + 0.03\,y$.

In like manner the total copper on the charge is the copper in the ores A, B, C, D (in this case 42 lb.), plus 2 per cent of the weight of the silicious ores. Therefore, the total copper in the charge is Cu in pounds $= 42 + 0.02\,x$. Further, in this special case it is calculated that 393 lb. of sulphur are in the ores of the charge, and if it is assumed that 85 per cent will be volatilized, there will be left 15 per cent for the matte, which amounts to 59 lb. In forming matte, Cu combines with one-quarter of its own weight of sulphur to form Cu_2S, because

At. wt. $Cu = 63.6$ $Cu_2 = 127.2$

At. wt. $S = 32.07$. $127.2 \div 32.07 = 4$.

Since the amount of Cu in the charge is $42 + 0.02\,x$, the amount of sulphur required by this amount of copper is $10 + 0.005\,x$, and the amount of sulphur left to combine with iron is $49 - 0.005\,x$. In forming the matte the sulphur combines with 1.75 times its own weight of iron to form FeS, because

At. wt. $Fe = 55.9$

At. wt. $S = 32.07$. $55.9 \div 32.07 = 1.75$.

The amount of Fe required to satisfy $(49 - 0.005\,x)$ lb. of S is, therefore, $86 - 0.009\,x$. The total Fe in the charge as per calculations, is 599 lb. from ores A, B, C, and D, plus 4 per cent of the weight of the silicious ore x, or $599 + 0.04\,x$. Therefore, the total Fe left to go into the slag will equal $(599 + 0.04\,x) - (86 - 0.009\,x) = 513 + 0.049\,x$.

The total lime (CaO) in the charge, all of which goes into the slag is 69 lb. from A, B, C and D, plus 6 per cent of the weight of the silicious ore x, plus 51 per cent of the weight of the lime-rock y. This equals $69 + 0.06\,x + 0.51\,y$. We have, therefore, three equations for the pounds of silica and iron and lime in the slag:

$$SiO_2 = 765 + 0.69\,x + 0.03\,y$$
$$Fe = 513 + 0.049\,x$$
$$CaO = 69 + 0.06\,x + 0.51\,y$$

In the chosen slag the ratio of SiO_2 to Fe is $44 \div 19.5$, while

the ratio of SiO_2 to CaO is 44 : 23. This gives the two equations

$$11.25\,x - 0.58\,y = 7700$$
$$13.20\,x - 21.71\,y = -14.570$$

From this we find $x = 1129$ and $y = 1056$, the pounds of siliceous ore and limerock respectively to be added to the charge.

Hence, the charge will consist of 2500 lb. ores A, B, C, D, 1129 lb. siliceous ore and 1056 lb. limerock, hence total weight 9685 lb. From the above equations we find that this charge will contain 1231 lb. SiO_2, 624 lb. Fe, 646 CaO, 55 Cu. The 55 lb. Cu in the charge will require 55 ÷ 4 = 14 lb. S for the Cu_2S in the matte. The remaining sulphur 50 − 14 = 45 lb. will require 45 × 1.75 = 079 lb. Fe for the FeS of the matte. Therefore, the matte will contain 55 lb. Cu, 50 S and 79 Fe. Assuming that these elements will comprise 95 per cent of the matte, the other 5 per cent being substances not considered, there results 2.3 lb. of matte, equivalent to a matte fall of 203 ÷ 3985 = 5.1 per cent. The resulting matte will assay 55 ÷ 2.3 = 27 per cent Cu. The slag will contain all the SiO_2 in the charge, 1231 lb., all the CaO in the charge, 646 lb.; the Fe in the charge, 624 lb., taken up by the S in the matte = 545 lb., which is equivalent to 699 lb. FeO. The slag is then composed of 1231 lb. SiO_2 = 43.9 per cent, 699 lb. FeO = 24.9 per cent, 646 lb. CaO = 23.1 per cent, which is the slag intended to be produced.

The method of calculation formerly used at the Garfield smelter is finally described. It consists in assuming the charge from past experience and the amounts which must be smelted, and calculating the resulting slag. The charge consists of 2000 lb. of bed-ore, 2500 lb. of ore B, 500 lb. siliceous ore, 500 lb. slag, and 500 lb. limerock. The amounts of silica, iron, lime, sulphur, and copper are calculated and carried out on the sheet. The volatilization of sulphur is assumed at 60 per cent. There is then left for matte 167.4 lb. sulphur. Copper in the matte requires one-quarter of its weight in sulphur, or 62 lb. Thus, 167.4 − 62 = 105.4 lb. S is left to combine with the iron of the matte. Sulphur requires 134 or 7/4 its weight of iron to form FeS. Therefore, 105.4 × 7/4 = 164.1 lb. Fe required. This amount leaves 995 lb. to go into slag. Since Fe is 7/9 of FeO, 995 × 9/7 = 1278.9 lb. of FeO in the slag.

The slag has now been determined. It contains 1786.0 lb. SiO_2, 1278.9 lb. FeO, and 699.0 lb. CaO. Assuming that these form 92 per cent of the total slag, and that the other 8 per cent is composed of Al_2O_3, ZnO, etc., 4319 lb. of slag result, whence the above quantities give 41.1 per cent SiO_2, 29.6 FeO, 21.0 CaO. The matte will contain 2.48 lb. Cu, 164.1 Fe, 167.4 S. Assuming that these constitute 95 per cent of the total, there is a matte fall of 610 lb., equal to 10 per cent. The copper in the matte is 40.6 per cent.

The above article is critically reviewed by Prof. L. S. Austin in the *Mining and Scientific Press* of Nov. 27. He remarks that in copper smelting, quite differently from silver lead smelting, a great variation in slag composition is permissible, and hence has risen a carelessness in the preparation of the charge. But this is no reason why not to compute a charge, however, when this has been done, the slag which is produced should be controlled by the eye as well as by analysis. Referring to the single silicate slag, which Mr Barbour proposes to use, Professor Austin says that in pyrite practice the metallurgist is chiefly anxious that his slag should carry specified quantities of silica (in this instance 44 per cent), and that the bases go as far as possible with the addition of no more dead limestone flux than needed. The total of SiO_2, FeO and CaO adds up in the present case to 92 per cent, while in practice the sum varies between 85 and 90 for Utah ores.

Various objections are raised by Professor Austin against details of the calculation of the Garfield slag. He states that he has "given up the work of the Metallurgy of the Common Metals (to charge calculations for iron, silver lead, and copper charges) based upon the trial method, which he has found practically the most used by smelter men. Since, in the final summing up, this computation is used to check the results, why not use it from the beginning?"

Zinc.

Effect of Impurities on Roasting and Distillation Process.—The various reactions which are caused by impurities in the roasting of zinc sulphide ore and in the reduction and distillation of zinc oxide are the object of a paper by V. Lepiarczyk in *Metallurgie* of July 8, 1909. The experiments were made on a rather small scale, the charges were made up not from ore, but from pure materials, and the influence of different additions was investigated in succession. In roasting pure zinc sulphide it is possible to drive off all the sulphur, if the conditions are such that any zinc sulphate which is formed during the roasting process is destroyed and SO_3 and SO_2 are carried off. If in the roasting process in practice not all the sulphur is driven off, this is due to the presence of iron (Fe_2O_3 or FeS) and limestone ($CaCO_3$). The iron is less detrimental. The presence of Fe_2O_3 manifests itself in two directions: firstly, it causes some of the ZnS to remain unchanged; secondly, there is a reaction between ZnS and Fe_2O_3 yielding FeS. The presence of lime is far more detrimental. While it does not prevent the complete change of the zinc sulphide into the oxide, yet the largest part of the $CaCO_3$ is changed into $CaSO_4$. This $CaSO_4$ not only represents a loss of sulphur, but it causes an agglomeration of the roasted blende when it is being stored so that it has to be crushed again; further, the $CaSO_4$ is reduced in the retort in the distillation process as will be shown later on. If iron is present in form of FeS together with $CaSO_4$, it prevents a small part of the zinc sulphide from being completely changed into oxide; the sulphur from the FeS itself is completely removed, but the $CaSO_4$ is not completely changed into sulphate. The results of this part of his research are summed up by the author in the statement that it is the Fe_2O_3 which prevents the complete oxidation of the ZnS, while the lime causes the formation of sulphate.

In the reduction process in the retort the reactions between the different materials which may be present were studied separately. If nothing but carbon and $CaSO_4$ are present, not the whole $CaSO_4$ is reduced to CaS, as some remains unchanged; but there are two reactions going on at the same time, namely, $CaSO_4 + 4\,C = CaS + 4\,CO$ and $3\,CaSO_4 + CaS = 4\,CaO + 4\,SO_2$. In the second experiment nothing but carbon and zinc sulphide were present, while it is generally supposed that zinc sulphide is not reduced, this was found to be erroneous; some of the zinc and sulphur evaporates and the quantities of Zn and S evaporated are in the ratio of their atomic weights. In the third experiment the reaction between carbon and FeS was studied and it was found that FeS is even more attacked than ZnS. It seems that the two reactions which take place in the second and third experiment are $2\,ZnS + C = 2\,Zn + CS_2$ and $2\,FeS + C = 2\,Fe + CS_2$. This is interesting for practical purposes since it shows that the FeS is really not so dangerous as is generally supposed because only little FeS remains back in the roasting process, and the greatest part of this is decomposed in the retort. In the fourth experiment the reaction between Fe_2O_3 and ZnS was investigated, and it seems that the complete progress of the reactions is given by the formulas $2\,Fe_2O_3 + 7\,ZnS = 4\,FeO + SO_2 + Zn + 3\,ZnS = 3\,FeO + Fe + ZnO + SO_2 + 3\,ZnS = 3\,FeS + Fe + 4\,ZnO + SO_2$. The author then studied the reactions between more than two materials. If carbon, zinc sulphide, and Fe_2O_3 are present together the reaction is $Fe_2O_3 + 2\,ZnS + 4\,C = 2\,Fe + 2\,Zn + 3\,CO + CS_2$. If carbon, zinc sulphide, and FeS are present the reaction seems to be $2\,ZnS + 2\,FeS + C = ZnS + Zn + FeS + Fe + CS_2$. While pure $CaSO_4$, when reacting with C, yields CaS and CaO and some non-decomposed $CaSO_4$, yet when $CaSO_4$ is present together with ZnO, FeO, and MnO, there is formed only CaO besides some non-decomposed $CaSO_4$. The author concludes that the following reactions take place: (a) $CaS + ZnO = CaO + ZnS$, or (b) $CaSO_4 + ZnO = ZnSO_4 + CaO$ and, for

ther, $ZnSO_4 + 4C = ZnS + 4CO$, (c) $CaS + FeO = CaO + FeS$, or (d) $CaSO_4 + FeO = FeSO_4 + CaO$, and, further, $FeSO_4 + 4C = FeS + 4CO$, (e) while in presence of Mn the following additional reaction occurs, $FeS + Mn = MnS + Fe$.

The chief conclusion of the author which is of some interest for the practice is that the iron content in zinc sulphide is slightly detrimental in the roasting process because it causes a small part of the ZnS to remain unchanged. In the reduction and distillation process, however, the iron is very useful if it is present in form of Fe_2O_3 for two reasons: First, it changes any ZnS which has not been oxidized during the roasting process into oxide and thus makes it available before reduction and distillation. Secondly, when the $CaSO_4$ is reduced in the retort, the sulphur thereby liberated is caught at once by the iron oxide so that it cannot combine with zinc. If roasted blende rich in lime is to be reduced it seems useful to add some iron oxide in order to increase the yield of metallic zinc. But this would be unnecessary if it were possible to remove the lime from the ore before the roasting process, and this would be most advantageous, both for roasting and distillation. It should be tried to remove the lime by washing the ore in one process. If no calcium sulphate was present the content of Fe_2O_3 in the ore alone would be sufficient to change any remaining zinc sulphide to zinc oxide and thus permit its reduction and distillation.

Chemical Engineering.

Multiple-Effect Distillation.—At the recent Philadelphia meeting of the American Institute of Chemical Engineers two papers were presented on multiple-effect distillation. In a paper by F. J. WOOD (mechanical engineer of Marx & Rawolle's glycerine refinery), the various steps leading up to the present development of the art of glycerine distillation are described with particular reference to the fuel economy. The consumption of coal per pound of glycerine output is greater now than with the earlier system, as it has been found more economical to save glycerine from decomposition by the use of a flow of steam in a vacuum which greatly lowers the boiling point. In the multiple-effect apparatus, a superior economy of fuel is obtained by using but one flow of steam to a number of stills and condensers, the stills being arranged in series in regard to the steam flow—that is, the steam from the steam jet of the first still flows through a series of stills alternating with condensers, the condensers being maintained at a temperature that will condense glycerine out of the steam, but not the steam itself. The glycerine is forced through heaters by means of centrifugal pumps. The heaters are connected with the boilers and supply the heat necessary for the vaporization of the glycerine. From the heaters the hot glycerine is sprayed down through the steam.

The combined vapors of steam and glycerine pass into boiling water condensers whose temperature is maintained at such a point by means of a pressure regulator, that the glycerine, but not the steam, is condensed. The glycerine in condensing gives up its latent heat of evaporation to the boiling water. The steam passes on to the next still in the series to take up its quota of glycerine. Finally, after the last of the series of stills is passed, the steam, together with the volatile impurities, are condensed as sweet water in a cold water condenser. In order to maintain a uniform vacuum throughout the system, there must be a free flow of steam and glycerine vapor without obstruction. In this system, instead of forcing the steam down through the body of glycerine, the glycerine is pumped up and sprayed down through the steam and no back pressure to the flow of steam results.

The paper by A. C. LANGMUIR, also presented before the American Institute of Chemical Engineers, deals with the general advantages and applications of multiple-effect distillation. In the author's opinion the wood process of glycerine distillation marks one of the most important advances made in recent years in this line. The patent rights have been acquired by Marx & Rawolle, New York, in whose plant the process is now in successful use on a large scale. (See abstract above.) The fuel economy is marked, a considerable increase in output per still being obtained at a fuel consumption of less than half of that formerly used. A set of six stills in series is successfully at work with no diminution of efficiency in the last still as compared with the first.

The chief advantages of the process, aside from the fuel economy, consist in the ease of working, uniformity of product with varying crudes and the scientific control possible at all times. The process is largely automatic, less labor and less skill in handling being required. Only a small body of glycerine is present in the heaters, stills and connections, and the prolonged heating of large bodies of glycerine with resulting loss in the average still is avoided. The spraying of the glycerine through the steam avoids the shooting and foaming often met with when distilling certain crudes in the still generally used. The process is applicable in any distillation where steam is used and the product obtained has a boiling point higher than that of water, such as the distillation of the heavier products of coal tar and petroleum, of aniline, essential oils and the fatty acids of the candle industry.

Smokeless Combustion and Boiler Efficiency.—At the recent Philadelphia meeting of the American Institute of Chemical Engineers a paper was presented by A. BEMENT, Chicago, Ill., giving the results of tests carried out to ascertain the loss of heat due to incomplete combustion. The results are given in a table showing the comparative heat balance of an ordinary water-tube boiler in which the combustion was incomplete and an improved boiler arranged for the reception of a fire-brick tile furnace roof which made it necessary for the gases to travel to the rear of the boiler before coming in contact with the water tubes. By this arrangement, complete combustion was secured, as shown by the absence of smoke. The loss of heat due to incomplete combustion in the ordinary boiler was found to be 9.3 per cent, while in the improved boiler there was no loss. The method of making the determinations and calculations was given in full. In the second part of the paper, the causes governing the efficiency of a boiler were discussed, on the basis of the results of the efficiency of three boilers. The first was a well-known water-tube boiler in which the gases entered among the tubes at the rear and passed diagonally across the tubes to the exit. In the second boiler, a baffle was inserted among the tubes so that gases flowed twice the length of the tubes. In the third boiler, two baffles were inserted so that the gases flowed three times the length of the tubes. The fuel saving in the single-baffled over the plain boiler was 8.68 per cent, while the saving in the double-baffled was 20.68 per cent. Complete data with reference to the coal, temperature of gases, steam, draft, power development, etc., were given.

Oil and Grease Extraction.—In a paper read at the Philadelphia meeting of the American Institute of Chemical Engineers, Mr. W. M. BOOTH discussed the properties of the solvents which can be used for the extraction of oils, giving the solvent power and the cost of each. On this basis the cheapest solvent is found to be naphtha. The construction of building tanks and extraction apparatus was discussed. Methods of operation were given, also an account of the methods in use for the recovery of grease from garbage tankage and other waste products is given; drawings of extraction apparatus, and a number of tables and curves giving the properties of various fats and oils.

Utilization of Waste India Rubber.—In a paper read at the Philadelphia meeting of the American Institute of Chemical Engineers, Mr. S. P. SHARPLES gave a résumé of the various methods which have been employed in recovering the waste rubber of commerce, calling particular attention to the processes of the late Nathaniel Chapman Mitchell in the Philadelphia Rubber Works. Mr. Mitchell was the first to make a commercial success in this country of methods for utilizing worn-out rubber articles, such as boots and shoes. This was largely due to the fact that he discovered that sulphuric acid of 15° B.

to 25 lb. could be employed to remove the fiber from these goods without injuring the rubber. The process was at once stolen and utilized all over the country until at the present time it is used in many works.

Glass and Iron.—Although the formation of a special Chemical Reichsanstalt in Germany is contemplated some chemical research work is carried out at present at the Physikalisch-Technische Reichsanstalt in Berlin. From the report of the work done in 1908 given in London *Engineering* of Dec. 17, we notice briefly some of the more interesting chemical investigations. They concern first the weathering of crown glass by means of the cosin reaction, the glasses must not be dipped into the solution for much more than a minute, lest the lead be attacked in addition to the alkali. The firm of C. A. F. Kahlbaum has purified large bulks of iron nitrate, $Fe(NO_3)_3 + 9H_2O$, which is melted at 50 deg. Cent. and exposed to gaseous ammonia; dense red iron oxide and ammonium nitrate result. The latter is washed out and the oxide reduced and the powdery metal melted in the oxy-hydrogen flame. An iron rod thus prepared contained 0.001 per cent of manganese, 0.004 per cent of copper, the same amount of nickel or cobalt, traces of carbon and silicon, and a few hundredths per cent of oxygen. Reduced oxalate, also from Kahlbaum, was less pure. The physical tests of this "nitrate" iron and of other iron gave the following results:

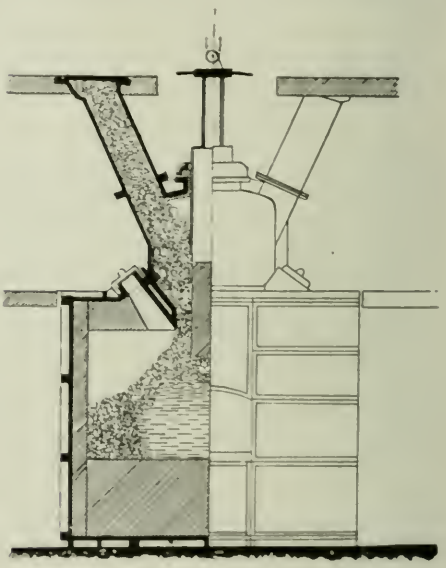
	Nitrate iron.	Kreusler wire.	Iron 0.1 per cent of carbon.	Steel 1 per cent of carbon.
Electric conductivity at 18 deg. Cent.	10	9.6	8.3	5×10^{-4}
Temperature coefficient of this conductivity	5.9	5.5	4.5	3.7×10^{-3}
Magnetic coercitive force	1.4	2.6		

This nitrate iron, which is superior to most electrolytic iron, will be valued by chemists for preparing their titration solutions and by physicists, but it is not a "pure" iron yet, of course.

Electrochemistry.

Large Electric Furnaces.—The tendency in electric furnace construction is toward a rapid increase of the size. This is clearly shown in the present development of the electric steel furnace and it is well known that the chief difficulty encountered in increasing the size is found in the construction of the electrodes. In the *Zeit. f. Electrochemie* of Aug. 1 R. Taussig describes the design of A. Helfenstein for large furnaces for calcium carbide manufacture. The size is limited by the amount of power which a single electrode or a compact electrode bundle can carry into the furnace. According to the results obtained in actual practice the maximum so far obtained is 2500 or 3000 kw. per electrode (30,000 to 40,000 amp. at 75 to 90 volts). For a three phase furnace with three electrodes this means a total capacity of 7500 to 9000 kw. or 10,000 to 12,000 hp. A further step has been made in the design of a double three phase furnace in which six instead of three electrode bundles are placed in the same furnace shaft. This means two separate three-phase units in the same shaft, so that the capacity of such a furnace is 15,000 to 18,000 kw. corresponding to a production of 80 to 110 tons of carbide in 24 hours in one furnace. With such large furnaces the heating effect of the reaction gases of the furnace becomes very great and must be taken care of in order to protect the workingmen and the connections to the external current. Further the smoke becomes troublesome (with ferro-silicon even more than with carbide). The greatest difficulty is, however, found in the method of charging the furnaces so as to arrange the charge properly around the electrode. It seems advisable with large furnaces to build them air-tight so that the smoke trouble is overcome and the heat of the gases of the reaction can be usefully employed. The adjoining illustration shows a vertical section of a single electric hearth for 8000 to 10,000 hp. About 8 or 10 meters above the bottom of the furnace a special charging floor is arranged. At the top of the furnace there is placed a large and tightly closed mixing receptacle or hopper for the charge, through the center of which the electrode passes down. Its weight is 3000 to 14,000 kg. for 10,000 hp. During the operation the electrode is surrounded on all sides by the charge. The charging receptacle has a capacity of 5000 to 7000 kilograms and is connected by means of long pipes with the charging floor. The charge is continually supplied through these pipes into the charging receptacle and passes from there into the electric furnace. In order to control the exact supply of the charge into the furnace, but especially for the removal of any furnace troubles, there are provided in the furnace at the side of the hopper broad slits which can be tightly closed. For a large three-phase furnace of 25,000 hp. three separate electrode bundles are used. Each electrode corresponding to one phase is provided with its own charging arrangement. It does not seem, however, that this design of large furnaces has already been tried out in practice.

Silundum.—At the last meeting of the German Bunsen Society Dr. R. Varberg read a paper on the manufacture of silundum in a carborundum factory in Bodeo, Switzerland. The



LARGE CALCIUM CARBIDE FURNACE.

paper is printed in *Zeit. f. Electrochemie*, October 1. They prepare amorphous carbon articles by pressing or by other treatment so that they get the desired form and then heat them in electric resistance furnaces of the simplest type so as to subject them to the action of carborundum and sand, or carbon and sand, or to both acting together. The two reactions are $SiO_2 + 2SiC = 3Si + 2CO$ and $SiO_2 + 2C = Si + 2CO$. The silicon permeates into the carbon article and forms silundum. (Chemically this is the same material as what is called siloxicon by Dr. Acheson.) As has been mentioned in our columns, silundum is useful as an electric conductor at high temperatures, for instance, for electric heating apparatus, etc. The resistivity of silundum is about six times that of carbon. The temperature coefficient of the resistivity is negative, but very small. At 1000 deg. Cent. silundum according to its constitution, has a resistivity of one half or two-thirds that at ordinary temperature. Silundum articles can stand temperatures of 1600 deg. for a long time without crystallizing and for short periods even temperatures up to 1700 deg. Above 1700 deg. silicon evaporates, yielding a white vapor of SiO_2, while the carbon remains back as graphite. Silundum can be heated to white heat and then immediately put into cold water without

cracking. It is also proposed to treat coke in the same way and to use the coke which has been changed into silundum instead of ferro-silicon in steel works. Silundum has been used as an electrode in electrolytic processes, but experiments on its use as a unit in sodium chloride electrolysis have not yet been concluded. Air attacks silundum even at the highest temperatures only in so far as a film of SiO_2 is formed. This protects, then, the internal parts.

Calcium Cyanamide.—It is well known that the formation of calcium cyanamide from calcium carbide and atmospheric nitrogen (which must first be separated from the oxygen) requires a temperature of at least 1000 to 1100 deg. Cent. in order to change all the carbide into cyanamide. It is true that the same reaction goes on at a lower temperature, like 800 or 900 deg. Cent., but it soon stops and it stops the earlier the lower the temperature. However, if a few per cents of calcium chloride are added to the carbide, a complete transformation of the carbide into the cyanide can be obtained at a lower temperature, like 700 or 800 deg. (process of Polzenius, German patent 163,320). Also, if some calcium fluoride is added to the carbide (process of F. Carlson) it is possible to obtain a product rich in nitrogen at 900 deg. Cent., while at 800 deg. Cent. the fluoride shows its favorable effect, but does not change all the carbide into cyanamide. A paper by F. FOERSTER and HANS JACOBY in *Zeit f. Electrochemie*, Nov. 1, is quite interesting as it shows that the action of the calcium fluoride addition is essentially different from that of the calcium chloride addition. If the quantities of calcium fluoride which are added are varied it makes practically no difference if only the heating process is carried on for a long-enough time. Whatever the amount of calcium fluoride added, the absorption of the nitrogen by the calcium carbide remains limited at 800 to 860 deg. The amount changed to cyanamide is the same whether 1, 2, 5 or 10 per cent of fluoride are added. The amount of the addition of fluoride determines only the speed of the transformation of the carbine into cyanamide. The formation of calcium cyanamide evolves considerable heat, but it is remarkable that the temperature attained by the charge containing calcium fluoride is less than that of charges without any additions or that of charges to which calcium chloride is added. In the latter cases the temperature may rapidly rise to 1000 deg. Cent. If, however, an addition of calcium fluoride is used, the temperature remains near 900 deg. Cent. The addition of calcium fluoride has, therefore, not only the advantage that it reduces the reaction temperature by 100 deg. Cent., but it permits a more quiet and more uniformed reaction. This is of importance when the retorts in which the process is carried out are heated from the outside. This has formerly been tried since in view of the relatively low temperature required electric heating was thought to be unnecessary. But as was described in our articles on the large new calcium cyanamide works in Odda, Norway, (our Vol. 7, pages 212, 309 and 360), it has been found preferable to use relatively small units and to heat them from the inside by electric resistors. Under these circumstances it is not necessary to use any addition in order to reduce the temperature of the reaction. But the present authors think that the addition of calcium fluoride might have the advantage of providing greater uniformity and regularity of the process. It is known that when nitrogen reacts with carbide (especially barium carbide) not only cyanamide but cyanide is formed. In this respect the addition of calcium chloride has again a different effect from the addition of calcium fluoride. With the fluoride some cyanide is obtained, with the chloride none.

Nickel Wire as Resistor for Laboratory Furnaces.—A paper by Prof. M. LE BLANC, read at the last meeting of the German Bunsen Society and printed in the *Zeit f. Electrochemie*, Sept. 15, gives details of an electric laboratory furnace in which nickel wire is used as a substitute for platinum. The results have been very satisfactory. In the discussion several speakers (among them Prof. Nernst) stated that they had obtained good results with nickel, but others complained of the great fragility of nickel. (The nickel-chrome alloy wire, made and used quite extensively in this country, would probably prove far more satisfactory for such work than pure nickel; it does not yet seem to have been introduced in Germany.)

Electrolysis of Alkali Chlorides.—A sketch of the development of the mercury cathode process in Europe in four successive types is given by R. TAUSSIG in *Zeit. f. Electrochemie*, Sept. 1. The original type—the old Castner-Kellner cell—was rocked. The cell had the great disadvantage that its units were too small, the current used for each cell being only 400 or 500 amp. The electrolytic plant with all accessories became therefore very large and somewhat complicated and the installation and attendance was expensive. The second type is the Kellner cell, which consists of three compartments, the chlorine compartment being in the center. The three compartments are connected together by siphons and pressure can be applied on the mercury in the two outer compartments by means of compressed air so as to force the mercury from one outer compartment into the middle compartment and then into the other outer compartment. When passing through the middle compartment the mercury alloys with the sodium which is being set free there. The anodes are platinum nettings, size 50 by 50 mm. They are arranged in electrode boxes of concrete which have proved more successful than the old clay boxes. Each box contains 88 platinum nettings so that each chlorine cell contains 528 platinum nettings of 525 grams weight, their capacity being 4000 amp. In the two outside compartments cathodes of cast-iron grids are placed. The third type is the Kellner-Solvay cell, which is now in use in Jemeuppe in Belgium, Brescia in Italy, and Lubimof in Russia. The mercury is circulated with the aid of a wheel. This cell represents the largest unit. It was originally built for 6000 amp, but is operated now at 10,000 amp and the current may be increased even to 15,000 amp. The fourth type is a modification of the latter cell and the only difference is that the mercury is circulated in it not by means of a wheel but by by means of an Archimedean screw.

Electrolytic Bleaching.—The electrolytic bleaching process as used in this country employs essentially electrolysis of sodium chloride for the production of caustic soda and chlorine, the latter being changed to bleaching powder; bleaching solutions are then made from the bleaching powder. On the other hand, in Europe the direct production of bleaching hypochlorite solutions directly in the cell in which the sodium chloride is electrolyzed has assumed considerable proportions in practice. On the basis of considerable experience it is claimed that the directly produced hypochlorite solution has a better bleaching effect on cotton and textile fabrics than solutions made from bleaching powder. (A hypochlorite cell of this type is made and used in this country for laundry work.) On the other hand, there has been a difference of opinion concerning the bleaching of sulphite pulp. In a paper by B. FRASS in the *Papier Fabrikant*, Vol. 7, No. 10 and 11 (also in *Zeit. f. Electrochemie*, June 15) he reports on an investigation from which he concludes that in sulphite cellulose bleaching, too, the directly produced hypochlorite solution is more effective than a bleaching powder solution. The behavior is as though the active chlorine in form of the hypochlorite solution was more effective than in form of a bleaching powder solution. An exact explanation has not yet been found.

Formation of Storage Battery Plates.—G. JUST, P. ARKENASY and B. MITROFANOFF gave in *Zeit. f. Electrochemie*, Nov. 15, an interesting account of extended researches on the use of an addition of nitric acid or nitrates to sulphuric acid electrolytes for the rapid formation of positive lead accumulator plates. The formation of plane lead plates was first studied in pure sulphuric acid according to the process of Plante; the development of capacity was investigated and charge and discharge curves were plotted. Analogous experiments were then made with an addition of nitrate to the sulphuric acid. They

showed that the capacity could be quickly increased in this way and also showed a change of form of the charge and discharge curves. The authors endeavored to find the best amount of nitrate to be added, but had some difficulty because the active mass had a tendency to drop off from the plane lead plates. Nevertheless, the experiments showed that approximately a concentration of 30 grams of potassium nitrate per 2.8 grams of sulphuric acid per liter was specially favorable. If too much nitrate is added the tendency of the active mass to drop off is increased. The less the addition of nitrate the more adherent becomes the active mass. They also found that when nitrate is added a white lead sulphate film is first formed on the positive plates. All attempts to improve the adhesion of the active mass to the plane lead surfaces were successful. But it was found that when grids such as used in practice with a large surface (Grosse-Berli, chemnitzer) were treated in the same way with the addition of nitrate, it was possible to get the formation of an active material which would be sufficiently adhesive in practice. The more nitrate is added, the better is the porosity of the active mass formed, while the durability is diminished. Since both effects act against each other in practice, there must be a certain concentration of nitrate which is most suitable.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Removal of Phosphorus.—Probably one of the most interesting advances made in recent years in steel refining is disclosed in a patent by Mr. Ernest Humbert (Dr. Héroult's metallurgist who is at present operating the Héroult electric furnace plant of the U. S. Steel Corporation in South Chicago). The invention consists of removing the phosphorus, not as usual, as phosphate, but as phosphide. The claims made for the process are that there is less loss of time and labor than in the old process, that there is an increase in the amount of steel produced, and that there is a saving in the electrical energy required for the electric furnace. The invention consists in the use of an oxidizing slag in such a way as to combine with the phosphorus and form a phosphate, and the adding of a reducing material to the slag containing the phosphate to convert the latter into a phosphide. The reducing material, usually ground coke, floats on top of the slag and reduces the phosphate without interfering with the metal below. "The strength of combination of the phosphide is so great that the phosphorus cannot be separated out of it by the iron without its first being changed back to phosphate, and this cannot occur in a reducing atmosphere." The fact that the reducing atmosphere is required seems to necessitate the use of an electric furnace. The following example of the operation of the process in practice is given. An impure charge of steel from a bessemer converter was used, analyzing approximately phosphorus 0.10 per cent, sulphur 0.16, manganese 0.10, silicon traces, carbon 0.07. This was transferred to a Héroult electric furnace. A black slag containing 400 lb. of mill scale and 400 lb. of lime was added to a 15 ton charge of steel, making an oxidizing slag, which became fluid when the steel below was thoroughly oxidized and all the phosphorus had passed into the slag as phosphate of lime ($P_2O_3(CaO)_3$). Upon this slag containing the phosphate of lime was added ground coke, which floated thereon and reduced the phosphate therein, forming calcium phosphide (P_2Ca_3). Thereupon, without removing the slag, the desired additions (silicon, manganese, etc.) were made to the molten steel. There was no return of phosphorus to the steel, and the final product contained phosphorus 0.015 per cent, sulphur 0.005, with carbon from 0.05 to 1.50 and silicon and manganese ad libitum. (943,192. Dec. 14, 1909.)

Electric Steel Furnace.—As was noticed in our June issue, 1909 (vol. 1, page 251), Mr. C. A. Keller has abandoned the type of electric steel furnace formerly employed by him, in which the current passes from one electrode above the bath into the bath and out of it again into another electrode above the bath (the well-known Heroult type). He now employs, like Mr. Girod, only one electrode at the top, or if he uses several electrodes they are all connected in parallel; the other terminal is the bottom or the hearth of the furnace. The current, therefore, passes from the electrode at the top into the bath and leaves the furnace at the bottom. For this type a durable construction of the furnace bottom is, of course, all important. In a recent patent of Mr. Keller a bundle of iron bars is placed vertically in the furnace bottom and are all connected electrically to a conducting plate arranged below their bottom ends. Between these bars and around the bundle which they form is strongly rammed in a refractory earth, preferably magnesia earth. The furnace bottom consists, therefore, half of vertical iron rods and half of magnesia earth. The latter also becomes a conductor at high temperatures. (941,419. Nov. 30, 1909.)

Electric Reduction Furnace for Iron Ore.—The Swedish electric reduction furnace for iron ore which has been described repeatedly in this journal (see especially the article by Yngstrom, page 11 of this issue) is patented by E. A. A. Grönwall, V. R. Lindblad and O. Stalhane. It will be sufficient here to quote the first claim, which relates to "the combination in an electric furnace with the heating chamber and the stack communicating therewith, the chamber being organized to provide a free space between the charge and the top of the heating chamber when the charge is introduced into the chamber and into the lower portion of the stack, of electrodes entering through the wall of the chamber and extended to pass through the said free space with their end portions immersed in the charge, and means for drawing gas from the upper part of the furnace and passing such gas into said free space portion of the furnace." (943,224. Dec. 14, 1909.)

Copper.

Converter Construction.—In customary practice of bessemerizing copper matte, a silica lining is used; it has the disadvantage that it reacts with the iron present to form a slag, so that the lining must be frequently renewed. If a non-corrodible basic lining is used, made of magnesite or chrome brick, etc., there results a considerable expansion under the influence of the high heat, and this expansion continues practically throughout the life of the lining, which should last for several months. The usual result is either disintegration of the lining or rupture of the converter shell. To overcome this difficulty, Mr. Wm. H. Peirce (Baltimore Copper Company) proposes to arrange the basic lining so that it is free to shift relatively to the shell so as to expand under the high heat developed in the course of treatment and at the same time preserve its continuity, while the tuyeres embedded in the lining have full delivery connection with the blast supply. In the first arrangement employing this scheme the tuyeres were flexibly sustained to shift with the lining to thereby avoid the breaking down of the tuyeres or the lining. Leaks through the lining, which would tend to disintegrate it, were thereby avoided. This arrangement has now been changed by Mr. Peirce in so far as the lining is shiftable as before relatively to the shell but the section of the lining in the immediate neighborhood of the tuyeres is anchored to the shell to form a zone in which there is no substantial shift. The cylindrical horizontal shell is open at its upper side to permit expansion of the lining, and is provided with a tuyeres, cylindrical, non-corrodible lining arched over at the open top of the shell and free to expand therein, and the set of blast tuyeres, extending

through the lining, is arranged longitudinally at one side of the shell. In such a converter the expansion of the lining is chiefly in a vertical direction or transerve to the axis of the shell. To prevent this shift in the immediate neighborhood of the twyers the section of the lining at one side of the converter and at the longitudinally extending twyer belt is anchored to the shell, the lining being otherwise free to expand in opposite direction from the twyer belt. The twyers are embedded in the lining and an abutment, or a series of abutments of metal, secured to the shell and extending into the lining, form a longitudinally extending shelf or barrier adjacent the set of twyers. (942,661, Dec. 7, 1909.)

Zinc.

Electric Zinc Smelting.—Mr. F. T. Snyder, who has already patented quite a number of different designs for electric zinc furnaces, has recently patented another one operated by three-phase currents. The furnace is of a narrow oblong shape and the three electrodes suspended from above are arranged in a row so that the side walls may be close to the source of heat. The hearth of the furnace is filled during operation with molten lead upon which rest the molten matte and slag. The furnace is open at the top to introduce the charge and permit the escape of the carbon monoxide gas which is burned at the top. The furnace is water-jacketed up to the top of the furnace to cool the upper portion of the charge. Powdered coke is introduced through a hopper surrounding the top of the electrode, while the main body of the charge is put into the furnace between the outer edges of this hopper and the water-cooled sides of the furnace. The zinc vapor rises in this outer part, but condenses on the water-jacketed walls "in liquid form rather than as dust." The condensed liquid zinc is withdrawn through drains consisting of thick hollow tubes of graphite, inserted in the walls and provided with a special water-jacket. The bores of these tubes are small so that they are completely filled by a small stream of liquid zinc. The zinc drops off at the outside into a well, which surrounds the lower part of the furnace and is at the bottom in connection with a molten lead receptacle in the hearth of the furnace. The advantage is that any of the heavier metals such as lead which may have been volatilized with zinc will settle in the well and join the main body of the lead in the bottom of the crucible. (942,110, Dec. 7, 1909.)

Deposition from Zinc Sulphate Solution.—In depositing zinc from sulphate solution by electrolysis, the electrolyte becomes gradually richer in free sulphuric acid and this results in part of the zinc deposit being redissolved from the cathode. Messrs. V. Engelhardt and Max Huth have found that this is due to impurities in the electrolyte (for instance, metal dissolved from the anode). They, therefore, employ a pure solution of zinc sulphate and an anode from which nothing is dissolved during electrolysis. This is pure massive or compact lead peroxide on a non-metallic support. If every other metal and even carbon be completely excluded the content of free sulphuric acid may be allowed to exceed 10 per cent without conversion or dissolution of the zinc already deposited. The patent is assigned to Siemens & Halske Company. (935,250, Sept. 28, 1909.)

Precious Metals.

Chlorination Process.—For the chlorination of refractory ores Mr. Wm. Koehler proposes to subject them to the action of hydrochloric acid in the presence of hydrogen at an elevated temperature, which must be below the temperature necessary for the volatilization of the metallic chlorides formed. The process is preferably carried out in a tube mill, hydrochloric acid entering together with the hydrogen. For commercial purposes very good results are obtained by using hydrochloric acid together with water gas, in which case the acid is acting in the presence of hydrogen and a carbon compound. (942,569, Dec. 7, 1909.)

Aluminium

Welding of Aluminium.—The Schoop process of aluminium welding by means of a special flux which simply serves to remove from the surface the otherwise present oxide film, but does not introduce any foreign materials into the weld, has been described in various articles in former volumes of this journal. A new improvement in the constitution of this flux is described in a recent patent of Mr. M. U. Schoop. It is a mixture of alkali chlorides with fluorides; for instance, potassium chloride 60 grams, sodium chloride 12 grams, lithium chloride 20 grams, cryolithe 6 grams. The materials are melted together and the molten mass is collected and ground to powder and then mixed to a thick paste with an aqueous solution of glycerine containing 5 to 10 per cent of glycerine. The proportions of the constituents of the welding compound are so chosen that the compound fuses at a temperature close to that of the melting point of aluminium. (943,164, Dec. 14, 1909.)

Light Metal.—Mr. J. G. Mellen patents a metal, consisting of aluminium 79 parts, magnesium 11 parts, phosphorized copper 10 parts. By phosphorized copper he means a metal consisting of 99.5 per cent copper and 0.5 per cent phosphorous. The metal, which he calls "duralum," is said to be adapted for general use as an anti-friction metal for bearings, etc., and for use in castings for motor cars, etc. It has approximately the same specific gravity as aluminium and "is very much harder and stronger, it being particularly adapted to resist great crushing strain. For the purposes for which light castings are required it is much superior to iron, as it will stand even greater compression and does not dent under blows, and while fully as light as aluminium it is wholly free from the objectionable qualities of aluminium." The metal is said to run freely in casting and to machine well. (936,339, Oct. 12, 1909.)

Aluminium Solder.—An aluminium solder, patented by Mr. G. Hartmann, consists of 80 per cent tin, 17 per cent aluminium, 0.7 per cent nickel and 2.3 per cent metallic magnesium. (938,422, Oct. 26, 1909.)

Another aluminium solder, patented by Mr. L. Goppman, consists of 49.05 per cent tin, 3.43 antimony, 26.09 lead, 20.31 zinc and 1.10 copper. (939,494, Nov. 9, 1909.)

Tin.

Detinning.—A new chlorine detinning process is referred to in a patent of Messrs. W. W. Murray and H. M. Fernberger, in which tin scrap is detinned by means of chlorine gas dissolved in carbon tetrachloride. The resulting stannic chloride also dissolves in the carbon tetrachloride. After the detinning process is completed the solvent containing the stannic chloride is withdrawn from the scrap. But a considerable percentage will be retained in the numerous interstices of the scrap, which is therefore washed again with fresh carbon tetrachloride. The stannic chloride may be separated from the wash liquid by water and the solvent recovered, an aqueous solution of stannic chloride resulting from the treatment of the wash liquid with water. After the wash liquid has been removed from the residues, the portion adhering to the residue may be removed by further washing the residue with water and by the application of heat. (943,986, Dec. 21, 1909.)

Tin from Tin-Lead Waste.—Mr. A. Nodon recovers the tin from tinned lead-plate waste, etc., by subjecting the metal waste to the action of a hot solution (40° C.) of stannic sulphate with the addition of sulphuric acid, mixed with an alkaline stannic haloid salt (ammoniacal bichloride of tin), which solution has no chemical action on lead. The tin is dissolved in the form of ammoniacal chloride of tin. The solution is electrolyzed between graphite anodes and pure tin cathodes with a cathodic current density of 1 amp to 2 amp per square decimeter. (940,471, Nov. 16, 1909.)

Electroplating.

Nickel Plating.—Dr. E. F. Kern, who has done considerable work on the theory and practice of electroplating, has invented a process of depositing nickel. A smooth, dense, coherent and adherent deposit of nickel may be obtained by the

electrolysis of a bath containing fluosilicate of nickel in solution, and particularly good results may be obtained by the electrolysis of a bath containing in addition to the fluosilicate of nickel either an alkaline fluoride, as ammonium fluoride, alone, or an alkaline fluoride and a soluble fluosilicate which is more basic than nickel, preferably aluminium fluosilicate. The electrolyte recommended by him is made as follows:

Water	100	or more	parts
Fluosilicate of nickel	10	"	"
Ammonium fluoride	5	"	"
Aluminium fluosilicate	5	"	"

Ammonium fluoride should be added to the bath from time to time during the operation of the process, in order to restrain the separation of the silica. (942,729, Dec. 7, 1909.)

Galvanizing Barrel.—To reduce the cost of electrogalvanizing by making the operation almost entirely automatic is the object of a patent granted to L. Potthoff, whose work along these lines has been described in an illustrated article in our August issue, 1907 (Vol. V, page 331). The arrangement contains a revolving barrel lined inside with cocoa-matting, in which the articles to be plated are constantly tumbling over each other, so that they are plated on all sides. When a sufficient coating of material has been formed, the direction of rotation of the barrel is reversed, whereby by an automatic device the plated articles are discharged from the barrel and passed through a chute into the washing drum. Upon further charging of the plating barrel with another lot of articles, and when the barrel is now being again rotated in the opposite direction, the articles collected in the washing drum are automatically discharged and carried successively through the draining drum, the sorting drums, and finally to the receptacles for shipment or storage. The operations of galvanizing, washing, drying and sorting (various shapes and sizes of articles being galvanized at the same time) are therefore automatic, and since a single attendant can manage a number of electroplating machines, the cost of attendance is greatly reduced. (941,535, Nov. 30, 1909.)

Nitric Acid.

Fixation of Atmospheric Nitrogen.—In the October issue, page 430, we gave an illustrated description of the Innsbruck plant where the Pauling process for the fixation of atmospheric nitrogen is in commercial operation. In this connection two recent patents of Harry Pauling are interesting. Since the process was described in detail in the article referred to, we simply give here the claims of the two patents. Patent 939,441 refers to "apparatus for producing electric discharges having in combination stationary electrodes with a distance between them large enough to prevent ignition, a conductor successively passing, and thereby alternately increasing and decreasing the distance between the said electrodes and blast pipes adapted to extinguish the discharges before short circuiting between the electrodes may occur." Patent 939,442 refers to the "process consisting in elongating the voltaic arcs produced at the place of greatest proximity of the electrodes by causing them by suitable means to propagate along the electrodes and in passing the gas to be acted upon by electrical discharges in currents of equal quantity and velocity in inclined direction against each other and meeting in the plane of the electrodes." (939,441 and 939,442, Nov. 9, 1909.)

A patent granted to Prof. Fritz Haber and A. Koenig, of Karlsruhe, and assigned to the Badische Company, is quite interesting because it digresses for good reason from orthodox principles. The chief features of their new process are the use of a reduced pressure and the intentional cooling of the arc. Lord Rayleigh had formerly investigated the effect of a change of pressure, but had found the yield to be almost independent of the pressure. The present authors have confirmed this if nothing but the pressure is changed, and if as high a temperature as possible is employed. They found that it is different, however, if the arc is cooled by artificial means. The reduced pressure assists this cooling since the discharge which at ordinary pressure possesses the shape of a thin rod, expands and approaches the walls of the apparatus, which, being cooled, help to remove the heat from the arc. In this way discharge flames can be produced which practically no longer possess the well known brown zone in which the nitric oxide is believed to decompose partially back again to nitrogen and oxygen. They use metallic electrodes or electrodes of magnesium oxide, calcium oxide, etc. The pressure is maintained at not more than half an atmosphere, while the apparatus is of such a shape that the inside is practically filled with arc flame, while the apparatus is cooled either by the natural escape of heat or by additional means of cooling. By this means the concentration of the nitric oxide in the gases leaving the apparatus is increased "and it is easy to produce gases containing from 9½ to 10 per cent nitric oxide when using air, and from 13½ to 14 per cent when a mixture of equal quantities of oxygen and nitrogen is employed." These yields of nitric oxide are obtained with it being necessary to cool the gases rapidly by removing them quickly from the sphere of reaction, for instance, by withdrawing them through metallic coolers. For instance, the aforementioned yields were obtained when the arc was burned inside a tube of quartz which was cooled with water and the air or mixture of oxygen and nitrogen entered and left the tube at a pressure of 90 mm mercury, and with the low velocity of 1.5 m per second. In order to prevent decomposition of the nitric oxide at the red-hot electrodes, the entry and exit tubes for the gases can be so placed that the layer of gases around the electrodes is not renewed. The sectional current density, i. e., the strength of the current per unit area of the cross section of the tube, should preferably be as high as possible. There are no sharp limits within which the pressure should be maintained. But no advantage is gained by reducing the pressure considerably below 80 mm mercury. In the first three claims the pressure is defined as "not exceeding that of half an atmosphere." (938,316, Oct. 26.)

Alloys.

Ferro-Titanium.—If ferro-titanium is produced with carbon as reducing agent the resulting alloy is rich in carbon, which is a clear disadvantage. If, however, silica is present the silicon reduced simultaneously with the titanium acts as a carbon excluding agent, and the alloy produced is low in carbon, but high in silicon. The silicon may be removed, however, by a following reduction with iron oxide, for instance hematite ore. Mr. F. M. Becket (Electro Metallurgical Company) proceeds, therefore, in the following way. He produces a low-carbon high-silicon ferro-titanium in an electric furnace from a charge of titanium oxide and silica, carbon, and iron or iron ore. To the high-silicon alloy thus produced is then added iron oxide, either in the same furnace or in a separate vessel, to effect the oxidation of silicon in the alloy with simultaneous reduction of the iron oxide. A low-carbon and low-silicon ferro-titanium is thereby obtained. For instance, a product containing about 30 per cent of titanium and 2 per cent of carbon, substantially free from silicon, may be made by reacting with ferric oxide on an initial alloy containing about 50 per cent of titanium, 40 per cent of silicon, 3 per cent of carbon and 7 per cent of iron. A product containing 30 per cent of titanium and 5 per cent of carbon, substantially free from silicon, may be similarly made from an alloy containing 41 per cent of titanium, 22 per cent of silicon, 7 per cent of carbon and 30 per cent of iron. (941,553, Nov. 30, 1909.)

Calcium Nitride.—A modification of the well-known Acker process is the subject of a patent of Mr. C. F. Acker. Instead of acting on the fused lead-sodium or lead-calcium alloy with steam (in order to produce the hydroxide) he acts on it with nitrogen and produces a nitride. The nitride is usually lighter than the lead and rises to the top, where it collects as a floating layer. Other nitrides can be made in the same way. (941,132, Dec. 14, 1909.)

A New Type of Distillation Machinery.

BY WALTER E. LUMMUS.

A continuous distilling column of unique design recently built by the firm of Walter E. Lummus, of Boston, Mass., for the U. S. Forest Service, and known as a three-product distilling machine, has shown results on operation which appear to warrant a brief general survey of this system of distillation.

The acceptance of the machine referred to depended entirely upon the successful outcome of a series of trial runs with a variety of materials especially selected to demonstrate the amplitude of operation. The results achieved appeared creditable in every respect and seemed to meet with the requirements of the Forest Service as well as to justify the hopes of the builder. The machine is now set up at the new Forest Products Laboratory lately established at Madison, Wisconsin, and is being used in the refining of large samples of crude wood turpentine. This work is being carried on in connection with a series of experiments undertaken by the Bureau primarily intended to lead to a more thorough utilization of the waste material resulting from the lumbering of the Southern yellow pine.

Machine Versus Apparatus.—Practically all distilling apparatus has hitherto been designed to obtain profitable results through the skill and judgment of expert operators. The financial return from such operations varies therefore with the diligence and care with which the work is conducted. But in all the more progressive arts, automatic machinery is taking the place of hand work because more reliable and more economical. The object of the Lummus distilling machine design is a compact, self-contained, and automatic machine, capable of performing work equal to that of the most skillful operators and of performing the work.

Construction.—The accompanying cut illustrates a machine capable of turning out not less than four refined products, simultaneously and in marketable condition. It is a form better adapted to general manufacturing conditions than the one built for the Forest Service, which was specially designed for experimental purposes.

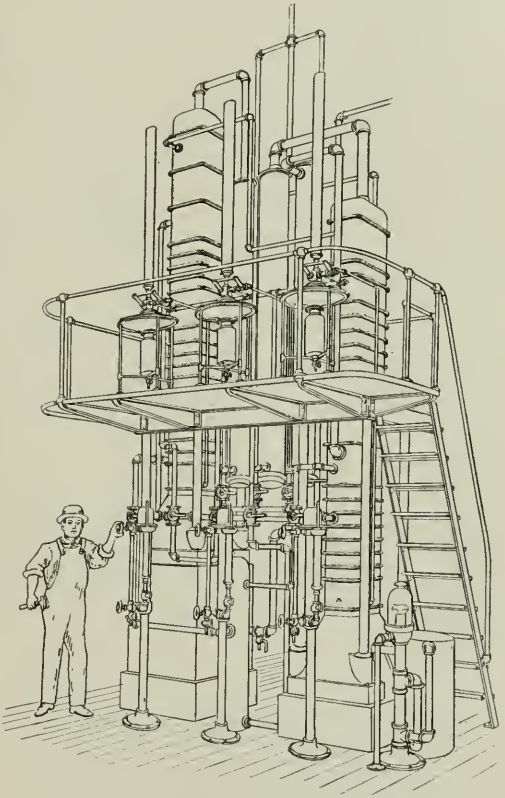
A complete description of this machine and the nature of the operations by which its work is accomplished would involve the study of multiple-effect cells and an understanding of the conflict of whirling masses of foam and vapor in what might seem hopeless complication. Really the process is one of orderly and selective evaporation and the apparatus has been reduced by scientific elimination to a sober and practical solution of what has been heretofore a vexatious and difficult task.

The machine as shown consists of two columns composed of unit sections made of suitable metals and built upon a unit system which provides for modifying the apparatus to the most favorable arrangement for the work to be performed. In the distilling chambers comprised in these columns are devices for causing the vapor to undergo fractional distillation and condensation, to the end that the ingredients of the crude material automatically assort themselves "like by like" and go their separate ways in the proportions in which they occur in the crude. Between the columns or upright series of chambers are suspended condensers at appropriate heights so that the products as they issue may flow by gravity into raised tanks from which, in turn, they may be drawn with convenience for shipping.

In front of the machine and at a height convenient for operation, are speed gauges or spiritometers especially designed for the purpose which show the rate of flow of each product, its gravity and temperature. Between the gauges is the switchboard or bank of operating valves, arranged with simple and methodical relation to the gauges so that the operator may observe his gauge and manipulate the regulation of the machine to the exact result desired.

The makers emphasize specially the simplicity of operation, the compactness, and workmanship of these machines in contrast with the complicated construction and enormous bulk of foreign apparatus intended to turn out similar products. In regard to compactness it may be well to add that the particular machine illustrated occupies a floor space about 3 ft. 6 in. x 7 ft. 6 in. and is 17 ft. over all. The capacity, on the other hand, is between 600 and 720 gals. of crude material in 24 hours, or 25-30 gals. per hour.

Operation.—Continuous distillation is not new in Europe, and there are simple continuous "beer stills" in modern American distilleries. The latter, however, are not depended upon to make finished products but only to concentrate material that is to undergo later more thorough rectification. The advantages of continuous operation will be obvious to everybody.



MULTIPLE-PRODUCT DISTILLATION MACHINE.

The distilling machine described is operated continuously and no boiler or kettle is employed, nor any system of tanks to hold liquors in various stages of completion. When once properly adjusted the material travels without pause through the various chambers, emerging from appropriate condensers according to composition. The operation may be continued indefinitely so long as a uniform supply of crude material, steam, and cooling water are maintained. Very sensitive regulators control the pressure and temperature and even the gradually diminishing head of the supply tank from which the raw material flows to the machine. To this feature of absolute control the uniformity and improved quality of products are largely due.

The most remarkable feature of this machine, however, and one which perhaps indicates an entirely new development of industrial engineering, is the feature of "multiple products."

Not only is the main product isolated in pure condition from the complex extract in which it occurs as "crude," but advantage is taken of the favorable condition of the residue while yet hot to further assort the mixed gases in compartments designed for the purpose. In this manner each component of commercial value is likewise isolated and flows from its respective condenser in a manufactured condition.

Economy.—The economy of operation of these machines is especially worthy of attention. Since the raw material enters only as fast as the products leave, it follows that the quantity of material present in the machine at any one time can be reduced to that actually undergoing distillation and the steam and water consumption are correspondingly small. By a further economy, without compensating disadvantage of any kind, the raw material is heated to boiling temperature before entering the machine proper, with the waste heat of the products or effluents. In ordinary stills, a quantity of material sufficient for the entire operation must be maintained at the boiling point throughout the entire period, thus consuming many times the fuel required for evaporation, and no practical means has been found to utilize the heat of residues or distillates except in rare and unimportant instances. The machines, as built, have a capacity, according to size, far in excess of all previous records. The interaction of gases and liquids, upon which the efficiency depends is here produced by devices employing several new principles of distillation, and the superior yields and quality are partly due to these improvements.

Cost.—Not only is the cost of manufacturing with these machines far less than with the usual equipment of stills and tanks, but even the first cost of installation is less with a consequent saving of interest, depreciation and repairs. The Lummus distilling machines require no special building construction.

To sum up, there are two main distinctions between these distilling machines and the ordinary apparatus of well-known form.

Firstly, this new type may be termed a machine in every sense of the word, being compact, self contained and automatic. It is especially designed to meet American conditions, which, owing to the high price of labor, tend directly toward automatic machinery.

Secondly, the elastic unit system employed in construction permits the adapting of these machines to the special requirements of any crude material. The most unusual demands may be met with an exactness that has heretofore been considered impossible.

These two points alone explain the ready application of the Lummus machines to a vast number of distillation problems. Wood alcohol, turpentine, petroleum, fusel oil, tar oils, etc., which for years have been manufactured by tedious periodic processes are with these machines easily separated in one continuous operation into their ultimate constituents or groups of constituents, conforming to commercial specifications. Furthermore, products that have heretofore defied economical manufacture on account of prohibitive cost of periodic refining, are now brought within the range of profitable production.

Slime Filtration.

A new filter press placed on the market by the Sweetland Filter Press Company (Ernest J. Sweetland, General Manager, Union Trust Building, Los Angeles, Cal.) is of special interest, as it is a pressure filter, but is designed to have the chief advantages of vacuum filters, especially from the point of accessibility and the convenience of having to open the filter chamber for cake discharge.

The general appearance of the Sweetland filter press is shown in Fig. 1. The press is assembled on a plant of about one inch per foot, while the filter leaves hang vertically.

In order to gain the advantages of accessibility, the Sweetland filter press (Fig. 1) is built up of a plurality of sections. Each section is practically complete in itself, and, all being alike, they are interchangeable. In this way the capacity of the filter may easily be enlarged at any time it should be desired, for the enlargement of the filter merely requires the addition of more sections, and any number may be inserted by lengthening the tie rods sufficiently to accommodate them.

Each section consists of a cast-iron frame, the upper portion of which is in the form of a rectangle, while the lower walls

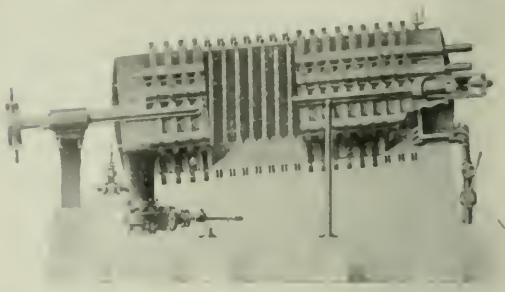


FIG. 1.—FILTER PRESS.

converge, forming a triangular opening in the lower part of the frame below the filter leaf (Figs. 2 and 3).

A special feature is the form in which the frames are cast; they have an I-beam section (instead of a rectangular or square section, as the old type of frames). In other words, there is a strengthening rib on the outer surface of the frame. This rib is in the form of a thin web of metal cast upon the outer wall of the frame, at right angles to it, with a bulb cast upon its outer edges. This construction results in great strength and light weight. While the main wall of the furnace is only about $\frac{3}{4}$ in. thick, the frames stand an internal pressure of 100 lb. per sq. in. without injury.

Fig. 2 shows one of the frames. Both sides of the frames are planed to a smooth, flat surface. On one side a groove $\frac{1}{4}$ in. deep and $\frac{1}{8}$ in. wide is cut into the frame, into which a rubber gasket $\frac{1}{8}$ in. square is inserted, which abuts against the flat side of the adjacent frame. This gasket is firmly impressed within

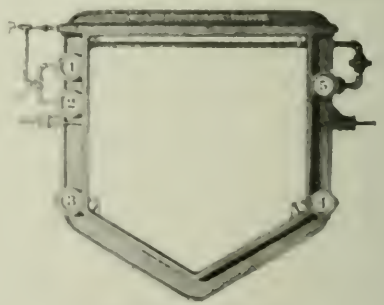

FIG. 2.—FRAME SECTION.

the groove, and forms a water tight joint up to 100 pounds pressure per square inch.

The spray pipe is clearly shown in this figure, extending horizontally across the top of the frame just below the upper wall.

There are five circular openings or passageways through each frame. When the frames are aligned in position in the press these passageways form continuous conduits throughout the length of the press and terminate in pipe connections at the upper head.

When the filter leaf is in position (Fig. 3) it is connected by a union to the frame at the upper right hand corner. The upper

left-hand corner is held in place by a small clip, while a pair of lugs attached to the frame support the two lower corners. The union and pipe connection at the upper right-hand corner brings the interior of the filter leaf into communication with the frame. There is a horizontal passageway through the top of the frame, which extends from one side to the other and terminates at the left-hand side in a pipe connection. Other pipe connections are provided leading into conduits Nos. 1 and 2 (Fig. 2), and join in a lever-handled three-way valve, the third opening of which connects with the pipe communicating with the filter leaf. The filter leaf may therefore be brought into communication with either conduit No. 1 or No. 2, according to the way the three-way valve is turned. The arrangement is plainly shown in Fig. 2.

A test-cock is shown on the pipe connection, the object of which is to provide separate communication with each leaf, so that in case a leak should occur at any time the filter leaf containing it may be immediately located and shut off from further filtration until such time as it is convenient to repair the leak or replace the leaf.

During filtration the three-way valve is turned to allow the filtrate to drain into conduit No. 2. At all times conduit No. 1 is kept filled with compressed air under moderate pressure, or water under a 12 to 2-foot head supplied by a pipe connected with the upper head of the press, and when it is desired to discharge the slime cake from the filter leaf the three-way valve is turned to allow the compressed air or water to enter the interior of the filter leaf from conduit No. 1, which causes the cake to drop instantly.

Each frame is provided with two small nozzles located near the lower corner of the leaf, which communicate with conduits Nos. 3 and 4 (Fig. 2), respectively. The object of these nozzles is to remove the last traces of slime which may adhere in the corners of the press after discharging. If the pressure of the pump is turned into these conduits for about 30 seconds after the bulk of slime has been discharged, the body of the press is left absolutely clean for the following cycle of operations.

Conduit No. 5 (Fig. 2) supplies the spray pipes with liquid. Each spray pipe is provided with an individual valve connection between the pipe and conduit, so the full pressure of the water supply available may be turned into all the spray pipes simultaneously, or into a few of them at a time, as may be desired. These spray pipes are not used in the ordinary cycle of operations, but for occasionally washing the filter leaves.

The filter leaf which is shown in place in the frame (Fig. 3)

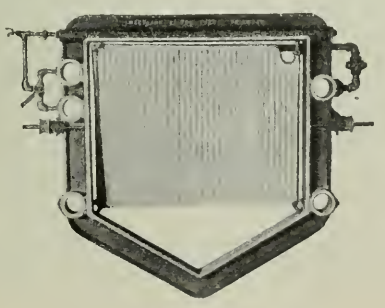

FIG. 3.—FRAME, WITH FILTER CLOTH.

comprises a series of vertical corrugated wooden strips covered with a layer of canvas, which forms the filtering medium. Each leaf is provided with a drain pipe terminating in a union outside of the leaf. To place the leaf in the frame it is only necessary to connect the union after inserting the leaf between the lugs at the other three corners. The filter leaves (standard size, 3 ft. 2 in. by 4 ft.) are so easily taken out and replaced in the frames that two men can easily remove a set from a 40-frame press, replace them with fresh ones, and have the press ready for operation again in about an hour.

The spray pipes are clearly shown in Fig. 1 between the filter leaves in the upper part of the press, and the discharge nozzles are shown entering from the upper head of the press, in line with the lower walls of the frame. There are five discharge nozzles, each ½ in. to ¾ in. in diameter, depending on the length of the press. All are controlled by a single quick-open-

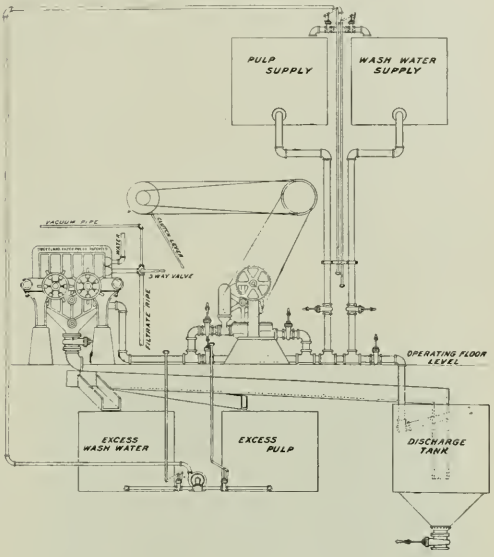

FIG. 4.—ARRANGEMENT OF FILTER PLANT.

ing valve on the discharge line of the plunger pump. The purpose of these nozzles is to flush the slime residues from the press when caused to fall from the filter leaves.

The discharge valve is plainly shown in this figure, attached to the hopper on the lower head of the press. This is an 8-in. quick-opening valve, and is used whenever it is desired to empty the press either of excess pulp or wash water, or when discharging the residues.

When the press is installed, there are three launders below the discharge valve; one for excess pulp, one for excess wash water and one for discharge. By means of a revolvable switch (not shown in Fig. 1) the discharge from this valve may be directed into any one of the three launders.

A suitable arrangement of a filter press plant intended for 100 tons' daily capacity is shown in Fig. 4. In this arrangement the filter press and pump which operates it are placed on a level below the pulp-supply tank and wash-water supply tank, and on another level just below the filter press are the excess pulp tank and excess wash-water tank, and a small centrifugal pump to return the excess pulp and wash water to the supply tanks on the upper level. By this arrangement the filter press is both filled and emptied by gravity, and the necessity of a large pump for rapidly filling and emptying the press is eliminated. A difference in level of 25 ft. between the supply tank floor and the excess tank floor is sufficient to permit of this arrangement, although more fall can be used to advantage if available.

The pump shown on the operating floor level is a triplex outside-packed pump, the size of which varies according to the size of the installation. This pump serves two purposes, viz., that of forcing the sludge or wash water into the press during filtration and washing, and to deliver water to the discharge nozzle while the press is being discharged. As a greater volume is required

during discharging than during filtration, the pump is so arranged as to have two speeds.

The filter press is first filled with pulp from the pulp supply tank through the by pass under the pump.

As soon as the press is filled the low-speed clutch of the pump is thrown in which forces the pulp into the press under 40 or 60 lb pressure. A relief valve is provided, which keeps the pressure from rising above the desired point. As the pulp is forced in, the clear filtrate passes through the canvas of the filter leaves and out through the conduit No. 2 into the filtrate pipe, and the slime is deposited on the surface of the filter leaves, forming a cake from 1 in. to 2 in. in thickness, depending upon the length of time the operation is continued.

When the cake has reached the desired thickness the pump is stopped and the three-way valve on the filtrate pipe turned so as to bring the vacuum pipe in communication with the interior of the filter leaves, the object of which is to hold the cakes intact on the filter leaves while they are relieved of pressure. A vacuum of 5 in. only is rquired to hold the cakes in place. The swivel joint or switch, just below the discharge valve, is now turned to direct the flow into the launder leading to the excess pulp tank, and the discharge valve is opened to allow the excess pulp to rapidly drain out the press.

The discharge valve is then closed and the press filled with wash water (or barren solution, as the case may be) through the by-pass. When the chamber of the press has been filled the pump is again started at low speed, pumping the wash water through the cakes to displace the dissolved gold or silver values. The displacement is very rapid under 40 to 60 lb pressure, and usually takes about ten minutes.

The excess wash water is drained from the press into the excess wash-water tank, and the slime cakes may now be discharged as follows.

The switch below the discharge valve is turned into the discharge launder. The valve on the suction line of the pump, which leads to the cone-bottom discharge tank, is opened. The pump is started at full speed, which delivers a stream of water from the top of the discharge tank to the discharge nozzles under about eighty pounds pressure. There are five of these nozzles, all of which are in operation at the same time, and a stream of water of high velocity is caused to sweep the bottom of the press. With these streams in operation all that is necessary is to turn down the lever handle upon each of the filter press frames, which causes the water or compressed air in conduit No. 1 to enter the filter leaves, causing the cakes to fall from the leaves to the bottom of the press, one at a time. As fast as they fall they are partially disintegrated and carried away by the streams from the nozzles into the discharge launder, which deposits the residues in the cone-shaped tank.

Each cake is given about ten seconds to fall before the next one drops, which is ample time for the leaf to become thoroughly cleaned by the reverse current through the pores of the canvas, and for the cakes to be carried away. Fresh water is not required for use in discharging the residue, but the discharging water is merely circulated from the top of the cone bottom discharge tank through the bottom of the filter press back to the discharge tank again.

In time a cleaning of the canvas becomes necessary, due to the formation of a deposit of lime and silica etc., which requires acid treatment and scrubbing of the canvas. For this purpose the Sweetland Filter Press Company have developed a special revolving brush for cleaning the filter leaves.

From tests made with the Sweetland filter brush it appears that the rate of filtration is practically in direct proportion to the pressure at which the liquid is applied to the filter surface.

Brazing Plant.

BY RICHARD N. HART.

Unless a broken iron casting is replaced by a new piece, there is one kind of repair that will restore its original strength. This is by brazing. A well-brazed fracture in cast iron adds from 10 to 25 per cent to the initial strength. This is because the brass amalgamates or alloys with both broken surfaces. Brass is stronger and tougher than iron.

It is generally much cheaper and quicker to braze a fractured casting than it is to buy a duplicate part. For this reason some of the larger foundries and machine shops have brazing apparatus of their own, or an independent brazing shop will be set up in the midst of a community of factories. Such a shop can make a large margin on its repair works and save a still larger sum for the manufacturer. Occasionally, when the part to be repaired is part of an apparatus of foreign make, the saving in time, anxiety and money may be very great. Every mining camp of any importance, at a distance from supplies, should certainly have a brazing outfit.

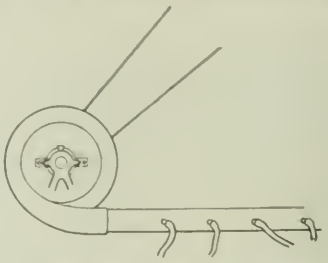

FIG. 1.—BLOWER AND AIR TUBE FOR BRAZING PLANT.

The brazing outfit here described can be installed in large shops, or can be set up in an independent repair shop. It consists of torches using gas and air blast, a makeshift brick oven and miscellaneous tools, such as a vise, hammer, files, wire brushes, etc.

The city gas at a pressure of about two pounds is used. The air blast is furnished by a rotary fan playing into a long cylinder, as shown in Fig. 1. The fan is driven by a 2-hp or 3-hp motor, and gives a pressure of six to eight ounces. As many as six burners can be attached to the air cylinder at once; for heating large castings this may be necessary.

The torch is a two-way gas pipe, Fig. 2, mounted on a tripod with a swivel joint and connected to the gas meter and the air cylinder by two wire wound rubber tubes. These tubes should be long enough to allow the burners to be moved about freely.

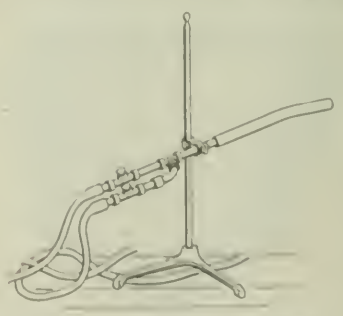

FIG. 2.—AIR-GAS TORCH FOR BRAZING.

The furnace may be made of loose brick built up around the casting so as to hold it in position and to contain the heat well. The table can be protected by asbestos cloth. The roof of the brick furnace can be held up with iron bars, as shown in Fig. 3, unless the casting is small enough to allow the roof to be made of one brick. The front of the furnace is left open and the torches are played directly into the front. No vent is needed

for the gases of combustion, because the crevices between the bricks are large enough, and the heat is thus better retained.

Briefly stated, a broken casting is repaired as follows: The fractured surfaces are brushed with a stiff wire brush, and the surfaces near the fracture are cleaned of paint, rust and grease with file, brush or waste. Paint the fracture surfaces with an emulsion of bronze filings, sal ammoniac, borax and water. Fit the broken pieces together and build the bricks up around the

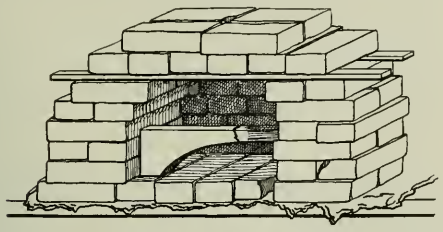

FIG. 3.—MAKESHIFT BRICK FURNACE FOR BRAZING, SHOWING BROKEN CASTING IN POSITION.

casting. Be sure that the pieces are fitted as firmly and closely as possible. They may easily separate slightly from the motion of the bricks while you are making the furnace. Next bring the mouth of the burner up to the open front of the furnace, point it toward the break in the casting and light the gas.

Regulate the air-gas mixture so that the flame has a distinct blue cone—*not purple*. If the casting is large, use two, three or more torches. When the metal is red-hot, apply additional flux to the fracture joint with an iron rod and rub it well along the crack. The flux is calcined borax or a mixture of calcined borax with sal ammoniac, salt, etc. Then shovel on a spoonful of brazing spelter, which will melt and run wherever the flux has cleaned the metal. Use plenty of spelter. Half-and-half brass may be used, or, better still, a brass of 70 per cent copper, which will be stronger and less apt to lose its zinc by burning.

The casting may now be cooled and cleaned. The cooling, like the heating, must be very carefully done if the casting is

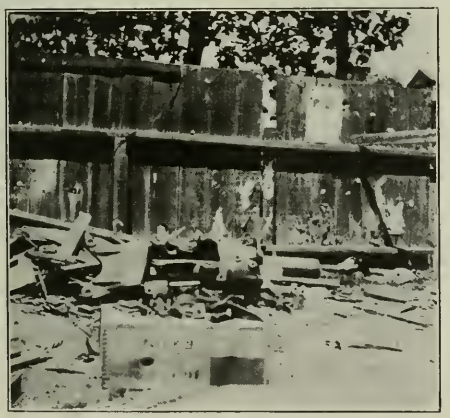

FIG. 4.—BROKEN MOTOR CYLINDER.

large or delicate or liable to break through expansion. Cast iron will gain in strength from 10 to 25 per cent by brazing, and will not break again in the same place. Steel, malleable iron, brass and bronze can also be brazed.

Figs. 4 and 5 show a motor cylinder that was broken into 33 pieces and brazed together by the Cast Iron Brazing Company, of Los Angeles, Cal. It was necessary to hold it together with wire. The entire operation took a little over two days. Care is necessary in heating up motor cylinders, otherwise they will have to be reground because of unequal expansion. Or if the flame is oxidizing (purple) it will rust the bore of the cylinder.

The cost of the apparatus can be brought within $400, or even $300. If the outfit is put up in the machine shop, and the power is taken direct from the shafting, a $150 motor can be dispensed with. If the outfit is put up at a mine, the gasoline blower from the assay office will take the place of motor, fan, cylinder and torch. In fact, it is a question whether a good gasoline torch would not be as safe, cheap and easy going as the outfit already named.

The Cast Iron Brazing Company estimate their gas and power cost at from 15 to 20 cents per hour for one burner, and about 10 cents additional for each extra burner. A casting of, say, 25-pound weight can be brazed in about one hour, counting cleaning before and after. The labor cost would be about 40 cents. The approximate cost of a one-hour repair job, provided the plant is in steady operation nine hours a day, is roughly as follows:

6 per cent interest on $400 apparatus	$ .01
10 per cent yearly depreciation on same	.02
Rent $200, taxes, insurance	.10
Power and gas	.20
Labor	.40
	.73

Between this cost and the average value of the casting to be

FIG. 5.—REPAIRED MOTOR CYLINDER.

mended there is a very wide margin, allowing a substantial profit.

Whenever this brazing outfit is needed it is badly needed. A mine, or any isolated plant using machinery, is sure to be tied up occasionally by the breaking of parts. Delay is always tremendously costly and exasperating. A trifling outlay, such as just described, will prevent breakages from demoralizing the plant.

Gas Velocity Recording Device.

A new velocity gauge for gases, which is being placed on the market by the Hydro Manufacturing Company, 720 Lewis Block, Pittsburgh, Pa., is interesting, as it is based on a novel principle.

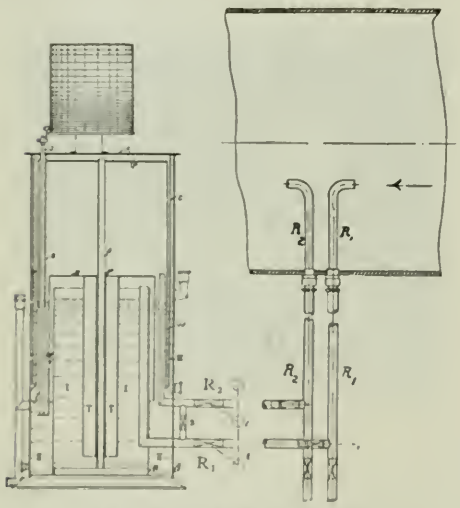
The gauge is shown in the adjoining diagram. The gas, the velocity of which is to be measured flows through the flue shown on the right hand, in the direction of the arrow. Within the path of the gas the ends of two pipes, R_1 and R_2, are placed. The open ends of both pipes are bent, but in opposite directions. That of R_1 is bent opposite to the flow of the gas, that of R_2 is bent in the same direction as the flow of the gas. This causes a difference of dynamic pressure in the two pipes R_1 and R_2,

and this difference of pressure depends solely on the velocity of the gas. By measuring the pressure difference, we therefore get an indication of the velocity of the gas.

The pressure difference is measured in the apparatus shown at the left. It consists in the main of two cylindrical compartments, one within the other. Both are partly filled with liquids, of which the inner one serves as operating medium and the outer one as a water seal. The inner liquid *I* carries a float *T* to the top of which is fastened an inverted cup-shaped cylinder *D*, which dips with its lower open rim *M* into the outer sealing liquid *II*. In this manner two independent gas chambers are formed, both of varying capacity, depending upon the depth of the immersion of the bell, which in turn depends directly upon the variation of pressure within and without.

A rod *S* that is centrally fastened to the bottom of the main cylinder serves as a guide for the operating bell. Its upper end passes through the removable cover plate *P'* of the apparatus.

The movement of the float or bell is carried outwardly by means of a second rod *J*. This rod is hinged to the lower portion of the bell and it passes through a tube *K*. The top end of this tube is secured air-tight to the cover, and its lower end dips into the sealing liquid *II*. The rod carries at its upper end a writing pen which bears against a rotating cylinder operated by clockwork, and thus serves to trace the varying differential pressures of the system upon a chart.



A VELOCITY METER AND RECORDER

An additional water seal *H* is provided for the cover by a cylindrical portion *C* extending therefrom downwardly into the sealing liquid *III* of an annular space, formed within the upper portion of the main body.

Communication between the gas main and the apparatus is established by two pipes *R*, leading into the air space below and *R*, leading into the space above the movable bell. Each of these pipes is provided with a stop-cock, 3, and both cocks are linked together to make them work simultaneously. By these means it is made possible to distribute the pressure to both sides of the bell at the same time. A three way cock serves to make communication of both air spaces in the apparatus with the atmosphere.

The filling of the three independent liquid chambers is accomplished through pipes which lead out from the main body of the apparatus. Plugs are provided for at the lower end of these pipes, which allow easily draining the receptacle if this should be necessary.

The velocity of the gas in the flue causes, as explained above, a difference of pressures in the two pipes R_1 and R_2, and this pressure difference causes the movement of the bell which is transmitted to the writing pen on the recording device.

This recording velocity gauge should be useful in gas works, producer gas installations, coke oven plants, blast furnace plants, and in general in metallurgical and chemical works in which the success of the process depends on a definite rate of supply of air or gas. Naturally the instrument is also useful in boiler plants, where it is employed to check the correct air supply for the most economical combustion of the coal; in this case the record chart indicates every operation of the fireman or of the automatic stoker, and serves as a guide to the fireman in which manner to obtain the best results.

Notes.

The **Zaremba Company**, builders of evaporators and chemical machinery, announce the removal of their engineering department and Eastern office from Philadelphia, Pa., to 1044 Ellicott Square, Buffalo, N. Y.

Corubin.—A valuable by-product, obtained in the production of chromium by the thermit process, is known as "corubin" (registered trade-mark), which has proved to be one of the best abrasive materials obtainable. It is used extensively abroad in the manufacture of high-grade emery wheels, emery cloth, and for other purposes where a first-class abrasive is required. Arrangements have now been completed for supplying the American market with this material, and the Goldschmidt Thermit Company, 90 West Street, New York, will be glad to give further particulars.

Helion Resistors.—The Parker-Clark Electric Company announces the retirement of Mr. W. G. Clark from his connection with the Company and the election of Dr. George M. Miller to the office of president and director. Prof. H. C. Parker continues at the head of the laboratory work. The offices of the company have been removed to the Lincoln Square Building, 1960 Broadway. The company is now placing on the market the helion resistors which are being made by the action of silicon on carbon for use as resistors in electric heating apparatus, etc. Anticipating a large demand for these resistors, the company plans to start a factory for their manufacture as soon as a good location can be selected.

A Study of the Open Hearth is the title of a very interesting little book just issued by the Harbison-Walker Refractories Company, of Pittsburgh. It is a concise and very clear treatise of the open-hearth furnace and the manufacture of open-hearth steel. The first and principal chapter deals with the open-hearth furnace and gives many useful data on refractories used in it. The other four chapters deal with fuels, the acid open-hearth process, recarburization, the basic open-hearth process and special processes (Talbot, Monell, Bertrand Thiel, Duplex). Some parts of the book deserve a more detailed review, which we reserve for a future issue.

The Palmetto Phosphate Company, of Tiger Bay, Florida, has recently put in operation its new producer gas electrical generating plant. The first of the three units was started Nov. 23, the second Nov. 26 and the third Dec. 2. Briefly, the equipment consists of one 1100 hp gas producer plant in three units, three 18 x 24 in. single-tandem gas engines direct connected to 800 kw. three-unit generators together with the necessary exciters, transformers, switchboards, etc. The entire plant is now electrically operated. The Allis-Chalmers Company are the builders of the apparatus.

Oxy-Hydrogen Welding and Cutting.—While the oxy-acetylene process has been introduced to a large extent in this country both for welding and cutting, the older analogous process in which the oxy-hydrogen flame is used, and which is employed largely in Europe, has been comparatively unknown in this country. A change in this condition is now to be made by the American Oxhydric Company, of Milwaukee, Wis., the owners of the American patents of the Societe l'Oxhydrique

Internationale for apparatus for the welding and cutting of metals by means of the oxygen-hydrogen flame. The American company thus has the benefit of years of experience with this apparatus in France, Germany, Belgium, Italy and Russia. The company manufactures the oxygen and hydrogen gases by electrolysis of water.

The **West Steel Casting Company**, Cleveland, O., who for the past three years have built up quite a large trade in medium and small steel castings made by the converter process, have lately enlarged their plant and are now installing crucible furnaces which will supply special small castings demanded by the automobile and general trade. The converter metal will be utilized as heretofore for casting of West's "electrical steel," which is largely used for dynamo frames and other electric castings. This same metal is also found valuable on account of its good strength and ductility for blank gears and general steel castings. The officers of the company are Mr. Ralph H. West (son of Mr. Thos. D. West), president; Mr. Everett W. Pike, vice-president, and Mr. David P. Lansdowne, secretary.

Cyanide Process in Mexico.—The first plant to be built in the famous Parral gold mining district of Mexico for the treatment of ore by the cyanide process has been decided upon by the Palmilla Milling Company, of Parral, State of Chihuahua. The plant is designed primarily for treating the ore of the Palmilla Mine; but will also be arranged for treating custom ore. The "Vetacolorada" or "red-vein" of the district is capable of producing many thousands of tons of ore of reasonable grade which can be treated successfully by cyaniding and concentration. The cyanide part of this new plant will include the best in filter and air agitation tank construction, though these latter details have not yet been decided upon. The machinery has been purchased from Allis-Chalmers Company, Milwaukee. Stamps are of latest design. The ordinary accessories such as grizzlies, crushers and conveyors are provided. All wearing parts were specified to be of specially tough steel. Three tube mills are included, which will be 5 ft. in diameter and 22 ft. long and will have the latest features of construction, such as automatic spiral feeders and ribbed liners.

Mr. **Elmer A. Sperry**, as has been well known, did a great deal of work several years ago in collaboration with Mr. C. P. Townsend to reduce to practice what is now well known as the Townsend cell for the electrolytic production of caustic soda and chlorine. This cell has now been in continuous successful use on a large scale for several years at Niagara Falls. It has not, however, been generally known until the present announcement that during this time of collaboration of Mr. Sperry with Mr. Townsend several further processes were developed and tested on an extensive scale. These include processes for the electrolytic treatment of ores in a fused bath, processes for the production of lead oxides, white lead (of low or high oil absorption), and pigments; also a process for tin ore treatment. These processes are said to have all the same characteristics as the caustic soda and bleach process of Townsend, namely, low first cost, directness of application, and economy of maintenance and power consumption. Further details concerning these processes may be had from Mr. E. A. Sperry, 40 Wall Street, New York City.

Obituary.

John Wellington Nesmith, president of the Colorado Iron Works Company, aged 76, died on Friday morning, December 17, of heart failure following an operation for gall stones. He had been in splendid health and attending to his usual business occupations until Monday, and his death came as a shock to his relatives and friends. Mr. Nesmith had been identified with the progress of the West from the early days, coming to Colorado in 1860, engaging in mining and milling in Gilpin County. He subsequently became interested in Langford & Company's foundry, the nucleus of the Colorado Iron Works, of which he became manager in 1879 and president in 1886. In the advancement in ore-treatment methods he took an active interest, and specialized in the blast-furnace smelting of lead and copper ores from the time of the first application of the process, achieving a world-wide reputation for the Colorado Iron Works in this line. Mr. Nesmith was a past master Mason and a past high priest of the Royal Arch Masons, vice-president for Colorado of the National Association of Manufacturers, a member of the American Institute of Mining Engineers, the Colorado Scientific Society, and of various other organizations.

Digest of U. S. Patents.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ELECTRIC FURNACES (Continued).

No. 643,898, Feb. 20, 1900, Harry M. Hill, St. Louis, Mo.

Resistance type. Oven for dental use, assaying and melting; an inclined crucible of fire clay or magnesia, having an external spiral groove receiving a doubled platinum wire of 36 gage, the groove being deeper than the diameter of the wire. The crucible is surrounded by windings of asbestos or mineral-wool paper, applied moist and baked. Before applying this paper the crucible is heated, and shrinks. The wire resistor is then rewound. The crucible is closed by a plate of refractory material, also grooved externally and receiving a resistance wire.

No. 645,284, March 13, 1900, Edward G. Acheson, Buffalo, N. Y.

Resistance type, for heating, roasting, and especially for purifying and graphitizing carbon. The furnace chamber is rectangular, two sides sloping at an angle corresponding to the angle of repose of the charge-mixture to an opening at the bottom, beneath which is a screw conveyor rotating in a water-cooled tube. Opposed electrodes pass through the walls of the chamber near its top. For the production of 500 lb. of graphite from coke per hour, the electrodes have a cross-section of 1250 sq. in. and are spaced apart 20 in., passing a current of 37,500 amp. They are composed of a number of rectangular bars arranged in contact. Pipes carrying water for cooling the product pass transversely through the lower portion of the chamber. The furnace has a suitable supply hopper, and vents which may lead to condensing chambers.

No. 647,614, April 17, 1900, Marcus Ruthenburg, Philadelphia, Pa.

Furnace for smelting and refining ores, comprising a chamber in the form of an inverted quadrilateral pyramid, formed of slabs of refractory material, opening beneath into a separate hemispherical crucible. Horizontal carbon electrodes pass through water jackets into the opposite sides of the chamber, preferably carrying 1000 amp per square inch of cross-section. The molten product, gravitating into the crucible, overflows through a spout at one side into a wheeled receptacle.

No. 650,040, May 22, 1900, Ernest W. Engels, Essen, Germany.

Bricks, slabs and plates of silicious, clayey or other refractory materials are rendered fire and acid proof by coating them with a layer of carborundum or other carbid, melted or fused on by an electric arc, for example, one of 200 amp at 110 volts. Either the pre-formed carborundum or the materials for producing it, sand and charcoal, may be placed on the surfaces of the bricks and then fused, uniting with the brick.

BOOK REVIEWS.

A Course in Inorganic Chemistry for Colleges. By **Lyman C. Newell,** Ph.D., Professor of Chemistry in Boston University. Half-leather bound, 604 pages, 89 cuts. Price, $2. Boston: D. C. Heath & Company.

General Inorganic Chemistry. By **Charles Baskerville,** Ph.D., Professor of Chemistry in the College of the City of New York. Cloth, 357 pages. Price, $1.50. Boston: D. C. Heath & Company.

A Laboratory Manual. By **Dr. Charles Baskerville** and **Dr. Robert W. Curtis.** Bound, 64 pages. Price, 40 cents. Boston: D. C. Heath & Company.

The absolutely best chemical text-book will never be written, so there is always room for a better one.

The books noted above are faithful attempts to improve on existing text-books, in the teaching of first-year college students. Of the first, we may say that it is a very carefully written work, following the style of the best of the older text-books, is a mine of information and is full of clear and convincing explanations, while not breaking away from the methods of the older text-books, we may say that it is certainly a most excellent *vade mecum* for the earnest, industrious student.

The second book is a "departure," an attempt to part company with the older type of text-book. The prevailing idea is "to accomplish the most in the least time." To this end, statements are short and precise, the style is even "sketchy," but in a bright student it should be attractive and inspiring. We would rather have seen the motive of the work "the accomplishing of the best use of the time available." The other principle is likely to result in superficiality, even in "cramming." But Dr. Baskerville's book and methods, under the charm of the personal enthusiasm of a similar teacher, will probably result in fascinating many young men with chemistry, particularly students of the quick, bright, city type, with which many schools and colleges have principally to deal.

Dr. Newell's book is conservative, excellent, reliable, and highly instructive; Dr. Baskerville's is radical, at places brilliant, not so reliable, but inspiring. The teacher will at once perceive that each book will be the best for certain classes of students.

* * *

The Elements of Metallography. By **Dr. Rudolf Ruer,** privat-docent at the University of Gottingen. Authorized translation by C. H. Mathewson, Ph.D., Instructor in Metallography at Yale University. Octavo, xiv + 342 pages, 119 illustrations. Price, $3 net. New York: John Wiley & Sons.

One is surprised and pleased to find that this work is not another contribution to the merely microscopic study of metals and alloys; in fact, the microscope is kept in the background throughout, being used for "supplementing the results of thermal investigation." The basis of the treatment is the thermal study of melting points and cooling curves, with all the deductions therefrom.

The physico-chemical theory is carefully and clearly explained. The one-component, two-component and three-component systems are systematically considered, the discussions being very lucid and interesting. This forms the bulk of the book.

Another chapter on "Practice" gives the technique of the thermal measurements, some very good advice on pyrometry and a brief description of preparing microscopic sections.

Altogether, it is a book for the thorough study and mastery of the best methods of investigation of metals and alloys. We agree with it entirely in putting thermal investigations in the first place and the microscope in the second place in the scientific study of most metals and alloys. We wish the work the acceptance and success which it richly deserves.

* * *

Lo Zinco. By Prof. **Roberto Musu-Boy.** 16mo., 230 pages, 10 illustrations, 4 diagrams. Price, 3.50 lire. (Retail price in New York, $1.25.) Milan: Ulrico Hoepli.

A well written, neatly printed, cheap book, which will undoubtedly advance the knowledge of the metallurgy of zinc in Italy. Parts I and II deal with the properties and metallurgical extraction of zinc, respectively; part III with the zinc mines of different countries; part IV with the uses of zinc and its alloys; part V with economic conditions in the zinc industry, and an appendix with the manufacture of zinc white.

While there are many shortcomings in the presentation, as far as concerns practice in other countries, there is much to be learned from the work, particularly concerning the zinc industry in Italy. We find, for instance, that Italy stands second to Germany among European countries in the value of zinc ore production, but behind six others in value of metallic zinc produced. This is because of the lack of cheap fuel and points the way to a large zinc industry as soon as the electric zinc furnace is through its "Kinderkrankheiten." About all that is said on this subject is that the furnaces of Casoretti and Bertani, working some years ago near Bergano, have a production of 3.25 tons of zinc per hp-year, using 250 kg of carbon for reduction per ton of ore and extracting 90 per cent to 92 per cent of the zinc. The author should have given considerably more space to the proposed electric zinc furnaces, because of their great prospective importance to his country.

The Reaction Between Silica and Carbon

We heartily join Dr. Acheson's many friends and admirers in extending to him our congratulations on the award of the Perkin medal, and we congratulate with equal sincerity the Perkin Medal Committee on its choice. The apparently simple reaction between silica and carbon was the starting point of Acheson's life work which has since extended and included all the different reaction products between silicon, carbon, and oxygen. Besides the three elements we have now silicon carbide or carborundum, silicon monoxide (Dr. Potter's monox) and silica, carbon monoxide and dioxide, and the somewhat indefinite series of compounds which Mr. FitzGerald calls silico-carbides and denotes by the formula SiC_xO_y. The temperature and the other conditions of the experiment decide what the end result of the reaction will be. While from a purely commercial and industrial standpoint these products have been brought into a very satisfactory shape, it would seem that much remains to be done by physical chemists from a scientific standpoint—above all the establishment of the possible equilibria. When this is done, American physical chemists could pay their debt to Dr. Acheson by devising an Acheson diagram for the silicon-carbon-oxygen system analogous to the Roozeboom diagram for steel.

The Effect of Heat Leakage on the Electrode Losses

In commenting on Dr. Forssell's paper in our last issue, we pointed out that the phenomenon of electrode losses in furnaces may be conveniently considered as a superposition of three phenomena. These are, first, the simple heat conduction due to the temperature difference at the two electrode ends as though no current was flowing; secondly, the Joulean heat set free in the electrode, which flows off impartially one-half into the furnace and one-half into the water-jacket on the cold electrode end; and thirdly, the heat leakage from the electrode into the surrounding furnace walls, which may be considered as being sucked impartially one-half from the furnace and one-half from the water-jacket. It may be interesting to consider how the simple formulæ which hold good if the leakage from the electrode into the walls is neglected, must be changed to take account of the heat leakage. We will use the notation of Mr. Hering's fundamental article in the October issue of last year (Vol. VII, page 442). To represent the heat leakage into the wall we denote by c the circumference of the cross-section of the electrode in inches, and by w the wall leakage coefficient, defined as the mean value of the heat in watts given off per second per square inch of electrode surface to the surrounding walls. Since L is the length of the electrode, cL is its lateral surface and wcL represents the total heat leakage into the walls or the surrounding medium.

* * *

One fact is at once evident. While both the Joulean heat and the simple heat conduction due to temperature difference

depend only on the ratio L/S of length to cross-section of the electrode, but not on the length or the cross-section separately, this is not true of the heat leakage into the wall, since this depends on the circumference (but not at all on the area) of the cross-section. It would, therefore, now be meaningless to try to find that value of the ratio of length to cross-section, for which the electrode loss would be a minimum, or that value of the ratio for which no heat passes through the hot electrode end in either direction (the two temperatures and the current being given). However, if the cross-section and its circumference are given besides the temperatures and the current, we can investigate in what way the electrode loss and its accompanying phenomena change with varying length of the electrode. The heat which passes from the furnace into the hot electrode end is $jkTS/L + \frac{1}{2}wcL - \frac{1}{2}C^2rL/S$. This becomes zero if $L = S\sqrt{2jkT/(C^2r - wcS)}$. The difference from Mr. Hering's equation is the term $-wcS$, which is, of course, zero, if the heat leakage into the walls is neglected. Further, the total electrode loss (which is defined as the sum of the heat given off from the cold electrode end into the waterjacket plus the heat leaking from the electrode laterally into the furnace walls) is $jkTS/L + \frac{1}{2}wcL + \frac{1}{2}C^2rL/S$, and this becomes a minimum for $L = S\sqrt{2jkT/(C^2r + wcS)}$.

* * *

As long as the leakage of heat from the electrode into the furnace walls is neglected, the condition under which the electrode loss becomes a minimum is identical with the condition of temperature equilibrium at the hot electrode end, no heat passing through this end in either direction. The above formulas show that this is no longer the case, if we take the heat leakage into the walls into account. In order to obtain temperature equilibrium at the hot electrode end, we must make the electrode longer or smaller in cross-section than would follow from the simple formulas in which the heat leakage into the walls is neglected. On the other hand, in order to make the electrode loss a minimum, we must make the electrode shorter or larger in cross-section than would follow from the simple formulas in which the heat leakage into the walls is neglected. But, after all, what we really should attempt to get is not minimum electrode loss, but rather maximum furnace efficiency. If the current, the resistance of the furnace charge, the cross-section and its circumference of the electrode, and the temperatures are given, then the condition of maximum furnace efficiency requires a greater length than the condition of minimum loss. Only when the resistance of the electrode becomes negligibly small compared with the resistance of the furnace charge, the conditions of maximum furnace efficiency and minimum electrode loss become identical.

* * *

For numerical applications, knowledge of the wall leakage coefficient w is all important, while practically no data is available. Nevertheless, we can draw in a general way the following conclusions. If we would base the calculation of the length of the electrode (cross-section, circumference, current, and temperatures being given) on the condition of temperature equilibrium at the hot electrode end, we get an upper limit for the length; since this upper limit we should not go, because we would then produce a temperature maximum somewhere within the electrode, and flowing off from this point of maximum temperature in both directions; there would then be great danger of destruction of the furnace walls by this excessive temperature. Nor would it be wise to select exactly this length for the electrode, because any accidental rise of the current above its normal value during operation would cause the same trouble. On the other hand, if we would base the calculation of the length of the electrode on the condition of minimum electrode loss, we get a lower limit for the length, below which we should not go because we would then only increase the loss without any compensating advantages. Nor should we select exactly this lower limit of electrode length because by increasing the length above this value (by a proper amount) we raise the efficiency of the furnace as a whole. If we remain between these few limits, we cannot be absolutely wrong, and it is at least comforting to know that the value of length found from the simple formulas in which the leakage of heat into the walls is neglected, lies between the upper and lower limits just discussed.

An Interesting Blast Furnace Experiment.

Mr. Gayley's famous large-scale experiment on the use of dry blast has opened a new era in blast-furnace operation. An even more revolutionary experiment is soon to be tried in a Belgian blast-furnace plant, with not only a dry blast, but with practically an oxygen blast (as noticed in an article on new uses of liquid air and oxygen, published in this issue). Such a process has been strongly advocated in this country by Mr. J. E. Johnson, Jr. While we do not know how far Mr. Johnson's process, as described and illustrated in our Vol. VII, page 38, will be followed in the Belgian works, it will be apropos to recall here briefly his chief arguments in favor of an oxygen blast. The principal gain would be the possibility of doing away with the heating stoves for the blast and with many of the accessories. Mr. Johnson further proposes to feed the carbon and the iron ore, not together, but in separate columns. The intention is to oxidize the carbon, by the oxygen blast, to carbon monoxide and to force the carbon monoxide through the iron ore, resulting in the reduction of metallic iron and the formation of carbon dioxide. The latter passes off through the ore column and preheats it, but it does not come again in contact with free carbon. In this way more of the carbon can be oxidized to dioxide than in ordinary blast furnace practice, and a better utilization of the calorific value of the coal can be obtained within the furnace itself. It will be interesting to watch the experiment in Belgium. In general, it is safe to say that any further reduction in the cost of producing oxygen gas will create new applications in industrial chemistry and metallurgy and will increase the demand. As an example of the interaction between different fields of activities it is peculiar that the chief impetus for the larger use of oxygen—our principal heat producing element—should have come from the development of low temperature (liquid air) apparatus.

A Question of Business Policy.

Managers of very large enterprises have different questions of business policy to solve which smaller firms are exempt from. When a firm or trust becomes so large or powerful

that it dominates the market supply of a commodity, the question of "fixing prices" arises; in other words, it has become master to a large extent of the law of supply and demand, in that one line. Such domination is usually based upon control of the main sources of supply and of the bulk of the machinery of distribution, in addition to the manufacturing features which are the original scope of the business. Given a firm in such a commanding position with respect to a commodity which the public needs and must buy in large quantities, be it beef or wheat, steel rails or coal oil, what are the principles which should actuate and determine the fixing of prices? Are they to be fixed at the utmost extent of the public's ability to pay, or at the reasonable limit of the company's ability to furnish?

* * *

Our business friends are familiar with the term "good-will." It probably existed on earth as a business asset centuries before "the angels sang it in." Certain it is that it is as highly valuable an asset in the balance sheet now as it ever was. Can trusts or monopolies afford to dispense with it? To come down to the concrete facts, can any firm or corporation afford to squeeze its customers to the last limit of their endurance, and thus forfeit their good-will? If an extra demand arises which causes a temporary shortage, is a corporation justified in temporarily putting up its prices, although its own manufacturing costs have not increased?

* * *

Many modern business men—the "public-be-damned" type—will answer these questions without hesitation by the simple affirmation "business is business." But, business is not business, as they mean it; it is horse-sense and common-sense and good sense applied to commercial life. The doctor who usually charges a certain sum for a certain service, and who doubles his fee because he was wanted more urgently, is not a sensible man, he makes enemies instead of friends. The shopkeeper who would charge me 10 cents for a 5-cent loaf of bread because I am extra hungry, is unprincipled, and gets no more of my future custom than I can help giving. The monopoly which "fixes prices" according to the demands of the market and not according to its cost price plus a reasonable profit, is working upon equally false and unfortunate ethical and business principles. By so doing, it is forfeiting the good-will of its customers, it invites competition, is provokes hostile legislation and stringent regulation; in other words, it antagonizes the general public good, and no business can permanently succeed upon such a foundation. A more secure business, a more permanently profitable business, a more honorable business can be built by cultivating the good-will of the public, by a "public-be-pleased" policy and by avoiding exploitation of its necessities. Short-sighted, self-willed, hard-fisted, penny-wise-and-pound-foolish some business men are, and they do not see the better way, the more honorable way—and in the end the really more profitable way, which best business sense and intuition sees and acts upon.

Two Recent Technical Advances in Steel Manufacture.

It has been said by cynical observers that patent specifications are often worded in a way so as to conceal rather than reveal their exact meaning. Nevertheless a patent, to hold good, must state the invention, and in spite of all attempts of hiding, and in spite of the many foolish things for which patents are granted, it remains true that the current patent literature contains most interesting live matter. Two quite recent instances with respect to steel making and refining are, a patent of Mr. E. Humbert for removal of phosphorus in the electric furnace, abstracted on page 48 of our January issue, and two patents of Mr. R. B. Carnahan, Jr., abstracted under Recent Metallurgical and Chemical Patents in this issue, for the production of a non-corrosive dead-soft steel of remarkable purity in the open-hearth. Mr. Humbert's patent is interesting in view of the recent statement of a very distinguished steel metallurgist that the electric furnace could do nothing new with phosphorus. It shows again how dangerous it is to argue *a priori* in such matters. To explain the new method of phosphorus removal, we may point out a certain parallelism with the method of removing the sulphur.

* * *

Sulphur in steel is chemically combined with iron and manganese. In the basic converter and the basic open-hearth these sulphur compounds will pass to a certain extent into the basic slag; and their absorption by the slag will be the greater, the higher the temperature of the slag and its basicity. But this absorption cannot be complete, as it must stop when equilibrium has been reached between the steel bath and the slag, because the sulphur compounds are soluble in both of them. The essentially new reaction which permits a practically complete removal of the sulphur in the electric furnace is the removal of the sulphur in form of calcium sulphide which is soluble only in the slag, but not in the steel bath. This seems at least the ultimate reaction in the electric furnace and because the calcium sulphide is insoluble in the steel bath, it is possible to drive the removal of the sulphur to any desired extent. If this reaction should occur in an open-hearth furnace, it could certainly not be the ultimate reaction on account of the oxidizing atmosphere which would change the calcium sulphide quickly into sulphate. This would react with the iron, causing the formation of iron sulphide which then passes back into the steel bath. It is, therefore, essentially on account of the reducing atmosphere of the electric furnace as compared with the oxidizing atmosphere of the Bessemer converter or open-hearth, that reactions eliminating the sulphur to any desired degree are possible in the electric furnace and impossible in the old metallurgical furnaces.

* * *

The removal of phosphorus in ordinary metallurgical furnaces with an oxidizing atmosphere is in the form of a phosphate. Mr. Humbert, by putting ground coke on the slag, changes the phosphate to phosphide, which is, of course, possible only on account of the reducing atmosphere of the electric furnace. It is impossible to do the same in an oxidizing furnace. The method is very simple, and, from what we have heard about its working in practice, it permits a very exact control of the phosphorus and results in a reduction in time, energy consumption, and loss of steel. The chief advantage seems to be that it is no longer necessary to scrape off the slag; this avoids much trouble and is important also for the construction of furnaces of large capacity. The electric furnace process is thus being worked out successfully in all its details and the chief problem to be solved in future seems to be to divide the whole

process of steel making into such a combination of different steps in different apparatus, that each reaction is carried out in the most suitable apparatus (according to whether it requires an oxidizing or reducing atmosphere, etc.) and that the practical efficiency of the whole combination process is a maximum.

* * *

The patent of Mr. Carnahan for making a dead-soft, open-hearth steel, of remarkable purity, as described under Recent Metallurgical and Chemical Patents, is interesting both with respect to its method of manufacture and its properties. There is absolutely nothing electrical about the method of manufacture as it is completely an open-hearth process, but in its first part—the reduction of impurities to the desired very low degree by continuing the process much longer than is usual in ordinary open-hearth practice and thereby overoxidizing the metal—the process is just like modern practice in preparing steel in the converter or open-hearth, preparatory for subsequent refining in the electric furnace. The really remarkable feature of the process of Mr. Carnahan is that what he does with this overoxidized steel appears to be simply to reduce the oxides by ferrosilicon, and to remove the gases by addition of aluminium in the mold. It is true that his steel when it leaves the furnace is very much hotter than in ordinary open-hearth practice and this may help in the accomplishment of the ends. It is a fact that when attempts have formerly been made to refine steel thoroughly by overoxidation, failure has always resulted from the difficulties of treating the overoxidized steel. These difficulties were successfully overcome by electric furnace treatment, but Mr Carnahan appears to have succeeded without such treatment and it is only to be regretted that the patent says so little about this most interesting feature of the process. The steel is on the market as American ingot iron and is used especially for sheets where its non-corrosive properties are of importance. The process seems to be rather expensive and it is a question whether it would not be cheaper to use a combination of converter and electric furnace processes since there seems no reason why it should not be possible to produce a steel of the same composition by such a combination.

* * *

The claim that this dead-soft steel is non corrodible appears to have been borne out in practice as far as the comparatively short time for which this steel has been in commercial use permits to draw conclusions. If the non corrodibility of this steel is further confirmed by experience, it will be a strong point in favor of the electrolytic theory of corrosion. It will be remembered that according to this theory, as proposed by Dr Whitney and elaborated and expanded by the extensive work of Dr Cushman and Dr Walker the intrinsic cause of corrosion must be found in the non-homogeneity of steel; this is probable to a large extent to the use of ferro manganese; on account of this lack of homogeneity there is a liability of some places in the steel surface becoming anodes and other places becoming cathodes in contact with moisture which acts as electrolyte, thus we have short circuited galvanic couples and corrosion results. Evidently, if this theory is correct then an absolutely homogeneous steel, free from impurities, slag inclusions etc. would be non-corrodible, as has been repeatedly pointed out in these columns. The makers of "American ingot iron" work on this principle; they do not use ferro manganese and in general endeavor to produce as pure a steel as possible. Let us hope that further experience with this steel will confirm the first good results obtained with it. It would be an indirect practical large-scale confirmation of the electrolytic theory of corrosion, and what is more important, the essential question would be definitely settled as to the direction in which we must work to find a practical solution of the corrosion troubles.

The Use of Pulsating Current for Electrolytic Refining.

It has long been looked upon as an axiom that direct current must be used for electrolytic processes. According to Faraday's law, the weight of the desired electrolytic reaction product is proportional to the coulombs passing through the cell in the proper direction. Theoretically, considering the reaction as perfectly reversible, we may conclude that by reversing the current and passing now the same number of coulombs through the cell in the opposite direction, the electrolytic reaction product of our former process is completely undone, so that at the end the system is in exactly the same condition as at the beginning. This will be true in practice, if the reaction products of the current passing in one direction remain within the zone of electrolytic action (for instance, do not pass off as gases out of the cell, etc.), and this condition will be fulfilled the more exactly the quicker the reversals of the current follow each other or, in other words, the shorter the period or the higher the frequency of the alternating current employed. In most cases of practice it is perfectly true to say that alternating current produces no electrolytic action.

* * *

The ingenious modification of the Wohlwill process of electrolytic refining of gold and gold-silver alloys, described in an article elsewhere in this issue, is exceedingly interesting, not only because it broadens very considerably the scope of the process, but because the very simple means of accomplishing this is the use of a pulsating current—a superposition of direct current and alternating current—instead of simple direct current. Everything we said above on the necessity of direct current for electrolytic action remains true in this case. The total refined gold which is obtained by deposition on the cathode equals exactly the amount which would be deposited if only the direct current were present. With respect to the output of refined gold the alternating current could just as well be absent. Why, then, is it used? Simply to break up the silver chloride layer formed at the anode, so as to avoid the necessity of mechanically scraping it off. The direct-current component of the pulsating current determines the gold deposition, the alternating-current component keeps the anode clean. In view of its remarkable practical advantages this process deserves attention far beyond the sphere of gold refining.

Lake Superior Iron Ore Values.

It would be interesting, although probably not particularly useful, to know what would have been the course of values if our Lake Superior iron ore deposits had been discovered in a country, like England, with an old established iron industry not subject to rapid growth on account of increase in demand. One

may well conclude that the history of prices would have been quite different from that which has been written. It was not until 1869 that pig-iron production in England passed the 5,000,000-ton mark, and not until 1906, 37 years later, that it passed the 10,000,000-ton mark. In the United States pig-iron production has doubled, on an average, just a trifle more frequently than once in 10 years. It is, of course, quite an elementary proposition that an increased demand for pig iron involves an increased demand for iron ore, and that the more rapidly the demand for pig iron increases, the more rapidly the demand for iron ore increases. There is a very marked difference, however, in the character of the demand for ore according to whether the demand for iron increases rapidly or slowly. It requires time to exploit ore deposits and develop mines to commercial production. If the increase in demand is slow, there is plenty of time to look around and develop the ore production. If the increase in demand is rapid, the time required for development becomes an important element, both because the ore is needed quickly and because, usually, rapidly expanding demand means very profitable prices, so that the ore buyer can afford to pay a premium for the quickness.

* * *

When the Mesabi range was discovered it appeared that an inexhaustible supply had been discovered, and values, as determined by the four older of the Lake Superior ranges, fell rapidly. The first Mesabi ore was shipped in 1892, contributing 4245 tons to a total output of the region of 9,082,370 tons. By the close of 1895 the range had passed each of the four older ranges in point of production, and in 1893 it shipped more ore than the other four ranges combined. For six years after values had become definitely established, or for the seasons 1894-99 inclusive, Mesabi non-Bessemer ore sold at an average price of considerably less than $2 a ton on Lake Erie docks, or at less than 50 cents at mine. Undoubtedly the industrial depression from 1893 to 1898, inclusive, had something to do with the low prices, but more in the direction of prolonging the period of low prices than in producing them. Before knowledge of the range was five years old it was certain that it contained enough ore to cover the country's entire pig-iron production, at the then obtaining rate, for 30 or 40 years. The first Mesabi ore was gained by doing little more than removing the sod. Had demand for ore increased only slowly the ore might have remained a drug on the market, but the rapid expansion in demand has made it so that stripping operations involving the removal of 75 ft. or 100 ft. of overburden are in progress.

* * *

While the greater portion of the Lake Superior ore deposits have passed to the control of consumers, there remains a large annual production by merchant interests which is sold in the open market, chiefly to merchant blast furnaces. Prices are fixed for each shipping season and do not change during the season. Ordinarily the great bulk of the season ore is sold in a few days or a few weeks. The relation between the price of ore and the prices of pig iron has undergone some remarkable changes even in the past few years, or since the general trade position of the Lake Superior ores became well established. The comparison given below is calculated to illustrate these changes. There is set down, first, the price of Mesabi non-Bessemer ore for seven seasons. Next is set down the prevailing price of No. 2 foundry pig iron, f.o.b. valley furnaces, at the time the principal ore selling was done. Next is given the average selling price of the pig iron during the approximate period of ore consumption. The year named is the year in which the ore was, or will be, shipped, the price having been named either in the early part of that year or in November or December of the preceding year, while the period of average pig-iron prices runs from May 1 of the year to May 1 of the following year.

MESABI NON-BESSEMER ORE AT LAKE ERIE DOCK, AND NO. 2 FOUNDRY PIG IRON AT VALLEY FURNACES.

Season.	Ore.	Pig iron at time.	Pig iron average.
1904	$2.50	$13.00	$13.93
1905	3.00	16.00	15.95
1906	3.50	17.25	20.28
1907	4.00	21.00	19.41
1908	3.50	14.50	14.78
1909	3.50	14.25	14.89
1910	4.00	17.00	.....

* * *

The pig-iron market has, as a rule, reflected the general state of trade rather than the cost of ore. Thus, the price of ore for the season of 1906 (which was fixed in December, 1905) was upon a market of $17.25 for pig iron, but the market advanced and from May 1 following for 12 months averaged $3 a ton higher. For the following season ore prices were fixed on a $21 pig-iron market; the market subsequently advanced to $25, in May, and declined to $15 in the following April. The actual realized price on the pig iron made from the 1907 ore was much less than is shown by the $19.41 average of quotations, for the reason that the great bulk of the pig iron was sold for forward delivery before the extreme advance occurred, the actual realized price probably being well below $19. As the price of ore is made at Lake Erie dock and the cost of transport has varied but little, the fluctuations in the price of ore at mine have been almost as large, absolutely, as the fluctuations at the point of delivery, while they have been much larger in point of percentage. What is particularly striking about the presentation given is the fact that relative to pig-iron, ore is much higher than ever before. In 1905 a $3 price was made upon $16 pig iron, but in 1908 a $3.50 price was made on $14.50 pig iron, and a year later the price was reaffirmed with pig iron 25 cents lower, while in 1906 a $3.50 price was made upon $17.25 pig iron. Again, the price of $4 was made only for 1907 and 1910, but in 1907 it came upon $21 pig iron, while for 1910 it came upon $17 pig iron. Thus with the great changes which have occurred in both ore and pig-iron prices, one trend remains distinct throughout, a higher and higher price for ore relative to the price of pig iron. The asset is the ore mine and not the blast furnace. Value depends upon the cost of replacement or duplication, provided there is need. One may readily conclude that, had there not been the rapid expansion in demand which has been experienced, values of Lake Superior ores would have remained upon a relatively low basis. As said before, for a period of six years in the nineties Mesabi non-Bessemer ore brought less than 50 cents per ton at mines. The present $4 price represents $2.50 at mines, since the rail freight from mine to Duluth is 80 cents and the lake freight through Lake Erie dock is 70 cents.

Nobel Prize for Chemistry.

The Nobel prize for chemistry has this year been awarded to Wilhelm Ostwald, of Germany. A full sketch of the life and work of Dr Ostwald has appeared in these columns (Vol. I, page 253). Since the publication of this article Dr. Ostwald has resigned his professorship in the University of Leipzig and has also devoted a good deal of his attention to the foundation of a new system of natural philosophy based upon energy as the fundamental principle. The result has been a remarkable volume of lectures on natural philosophy. Dr. Ostwald has also just published his book, "Grosse Manner," in which he attempts to analyze the elements of scientific greatness.

Lately, however, Dr. Ostwald has again favored the chemical world with several volumes on general chemistry, chiefly emphasizing the logical evolution of chemical science and scrutinizing its philosophical foundations.

Dr. Ostwald's many friends and former students on this side of the Atlantic have heard, with great gratification, of this last honor bestowed upon him.

Chemists' Club Plans Filed.

Plans have been filed with the New York City Building Department for the 10-story clubhouse and office building to be erected for the Chemists' Club at 50-54 East Forty-first Street. It will be an artistic edifice, of white marble in French Renaissance style, of the Louis XVI period, finished with Ionic pilasters and balconies at the second story and similar decorative balconies at the top story.

The main floor will contain in the rear a large auditorium with a balcony, and the second will be fitted as a lunchroom, with social rooms opening off from it. The fourth and fifth floors will be devoted to living and sleeping rooms for the members, below which will be the library and museum. The five upper stories will contain laboratories. The building is to cost $200,000, according to the estimate of York and Sawyer, architects.

American Chemical Society.

The annual meeting of the American Chemical Society was held in Boston during the last week of December. Over three hundred members attended. As Dr. Willis R. Whitney had declined re election to the presidency of the society, Dr. Wilder D Bancroft, of Cornell University and editor of the *Journal of Physical Chemistry*, was chosen to succeed him in that office. Dr Albert P. Hallock was re-elected treasurer and Professor Charles L. Parsons was re-elected secretary. Mr. Arthur D. Little, of Boston, Mass., Dr Leo H. Baekeland, of Yonkers, N. Y., and Professor W. L. Dudley, of Vanderbilt University, were elected councillors-at-large.

The meeting was a great success from a scientific and professional standpoint. The papers and discussions were of a high order, they will all be published in full in the different publications of the Society. Dr. Whitney's presidential address on "Some Chemistry of Artificial Light" proved particularly interesting and suggestive

The social functions of the convention were exceedingly enjoyable. Both the dinner and the smoker were well attended At the smoker Prof. Samuel C. Prescott was the soul of Section Q. Simply to indicate the good feeling that prevailed throughout, we quote here the speeches with which seven unsuspecting scientists were presented with "honorary degrees" at the smoker

"Harvey Washington Wiley—Doctor of philosophy, doctor of laws, doctor of [illegible] Thereof he [illegible] of the congress to be [illegible] on banquets, growth of [illegible] your name [illegible] your [illegible] your [illegible] Pure Food Products' and under [illegible] you, sir, the degree of LL.D., Doctor of Legal Lunch.

"Alfred D. Elbert—Physicist, statesman, man of affairs, efficient engineer, we appreciate your [illegible] as chairman of the committee of arrangements to make our brothers from other States remember the Hub. We bestow upon you the degree of C.O.D., Doctor of Chemical Organization.

"Charles Lathrop Parsons—Bachelor of science, inorganic chemist of note, famed for his exposition of the vagaries of Berrylium, consumed by a gnawing lust for numbers you have made our society the biggest in the world, we bestow upon you the degree which you so gracefully ornament, H.H.S., Hustling, Hornblowing Secretary.

"Wilder Dwight Bancroft—Bachelor of arts, author and editor. You range the field of sciences from divariant systems to cigars, from brain storms to brass. Your famous interpretation of Gibbs is so profound that Gibbs himself could not follow your analysis. You know you are great because we cannot understand you. We bestow upon you the degree of M.S.S., Many Sided Scientist.

"Marston Taylor Bogert—Master of science, doctor of laws, the mighty wielder of unconserved language, torturer of innocent atoms. You are a past master in forcing them to roll over, sit up and beg. I confer upon you the degree of L.Q.D., Doctor of Complicated Queeralogies.

"Louis Kahlenberg—Bachelor of science, author, enemy of fanciful imaginings. We admire you as a valiant fighter in a lost cause. I bestow upon you the degree of R.I.P., Promulgator of Revolutionary Ideas.

"Willis Rodney Whitney—Bachelor of science, doctor of philosophy, leader of America's chemists, trained in pure science, an expert in its application. I confer upon you the degree of E.M.F., Every Man's Friend."

American Association for the Advancement of Science.

Dr. A. A. Michelson, professor of physics in the University of Chicago, has been elected president of the American Association for the Advancement of Science, for the meeting to be held the end of the year at Minneapolis, Minn. Dr. L. O. Howard, of Washington, D. C., is permanent secretary of the Association; Professor Frederic E. Clements, of the University of Minnesota, was chosen general secretary, and Professor John E. Zeleny, of the University of Minnesota, secretary of the council. Vice-presidents of the sections have been elected as follows:

Section A—Mathematics and Astronomy—Professor E. H. Moore, University of Chicago; *Section B—Physics*—Dr. E. B. Rosa, Bureau of Standards, Washington, D. C.; *Section C—Chemistry*—Professor G. B. Frankforter, University of Minnesota; *Section D—Mechanical Science and Engineering*—Professor A. L. Rotch, Blue Hill Meteorological Observatory; *Section E—Geology and Geography*—Dr. John M. Clarke, New York State Geologist, Albany, N. Y.; *Section F—Zoology*—Professor Jacob Reighard, University of Michigan; *Section G—Botany*—Professor R. A. Harper, University of Wisconsin; *Section H—Anthropology and Psychology*—Professor Roland B. Dixon, Harvard University; *Section I—Social and Economic Science*—Hon. T. E. Mining and Metallurgical Congress

The International Congress of Mining, Metallurgy, Applied Mechanics and Practical Geology, of which a preliminary notice occurred in our issue of July, 1909 (Vol. VII, page 398), will take place at Dusseldorf, Germany, during the last week of June, 1910. The congress will be divided into four sections 1, Mining; 2, Metallurgy; 3, Applied Mechanics; 4, Practical Geology.

The presidents of the congress are Bergrat Kleine, president of the "Verein für die Bergbaulichen Interessen im Oberbergamtsbezirk Dortmund," and Kommerzienrat Springorum, director general of the Hoesch Iron & Steel Works, and president of the "Verein deutscher Eisenhüttenleute." The general secretaries are Dr Schrödter, secretary of the "Verein Deutscher Eisenhüttenleute", and Bergassessor von und zu Löwenstein, secretary of the "Verein für die Bergbaulichen Interessen im Oberbergamtsbezirk Dortmund."

There will be two grades of membership in the congress The first class of members are those who have become patrons of the congress through payment of a contribution of not less than 100 marks ($25). The second class of members is composed of those who pay a subscription of 20 marks ($5). The first-named class of members or patrons will be entitled to receive the printed reports of all proceedings of the congress in all different sections. The members of the second class, or ordinary members, will receive the reports only of that section in which they register. The proceedings of any one of the other sections will be obtainable by payment of an additional charge of 5 marks ($1.25) in each case.

The work of the congress will be performed in general meetings, at which papers of general interest will be presented, and

sectional meetings for the purpose of discussing important problems relating to more detailed fields, and by making visits to scientific and industrial institutions of interest and by excursions to districts of geological interest.

The program of Section II, that of metallurgy, is as follows:

A.—PRODUCTION OF PIG IRON.

1. Cooking.
   (a) Ovens.
   (b) Mechanical appliances.
   (c) Recovery of by-products.
2. Ore supply.
   (a) Recent discoveries of ore.
   (b) Recent development and prospects of the ore briquetting processes.
3. Metallurgy of the blast-furnace process.
   (a) Influence of foreign substances.
   (b) Composition of slag.
4. Blast furnace working.
   (a) Ore conveyance, storage and charging.
   (b) Gas washing and purification of the waste water.
   (c) Dry air-blast.
   (d) Casting machines and mixers.
5. Utilization of waste products.
   (a) Gases.
   (b) Dust from blast-furnace gases.
   (c) Slag (for hydraulic packing, cement, stone, concrete).

B.—PRODUCTION OF MALLEABLE IRON.

1. Advances in the methods of the metallurgical treatment of iron and steel.
   (a) Air blast refining process.
   (b) Open-hearth refining processes.
   (c) Processes for the production of electro-steel.
2. Production and treatment of special alloys of steel.

C.—IRON AND STEEL MANUFACTURE.

1. Improvements in the methods of casting iron and steel.
2. Further treatment of malleable iron.
   (a) Forging and pressing.
   (b) Rolling.
   (c) Fitting.
   (d) Development of the welding processes.
3. Driving of rolling mills considered technically and economically (steam, gas, electricity).

D.—TESTING OF IRON AND OTHER METALS.

1. Chemical testing.
2. Mechanical testing.
3. Metallography and microscopy of metals.

E.—ECONOMICS OF THE IRON INDUSTRY.

1. Iron trade statistics.
2. Labor conditions and labor supply.
3. Patent rights.

All inquiries for information regarding the sections or membership in them may be addressed to the Arbeitsausschuss des Internationalen Kongresses (Committee of Organization of the International Congress) Jacobistrasse 3/5, Düsseldorf, Germany.

The Institute of Metals.

The annual general meeting of the Institute of Metals was held at the Institution of Mechanical Engineers, Storey's Gate, Westminster, London, S. W., on Tuesday and Wednesday, Jan. 18 and 19, 1910.

The program contained the following papers:

C. O. Bannister, Esq., Assoc. R.S.M., on "The Use of Carbonaceous Filters in the Smelting of Zinc, as Employed in the Hopkins Fumeless Zinc Process."

G. D. Bengough, Esq., M.A., on "The Properties and Constitution of Copper Arsenic Alloys."

T. Vaughan Hughes, Esq., Assoc. R.S.M., F.I.C., on "The Failure in Practice of Non-Ferrous Metals and Alloys, with Particular Reference to Brass Loco-Tubes."

O. F. Hudson, Esq., M.Sc., and E. F. Law, Esq., Assoc. R.S.M., on "A Contribution to the Study of Phosphor Bronze."

C. A. Klein, Esq., on "Notes on a Suggested Record of Analyses."

Dr. Richard Seligman, Ph.nat.D., and F. J. Willott, Esq., on "The Analysis of Aluminium and Its Alloys."

Ernest A. Smith, Esq., Assoc. R.S.M., on "The Assay of Industrial Gold Alloys."

The first paper we print in full in this issue. Abstracts of all the other papers are included in the synopsis of Current Metallurgical and Chemical Literature in this issue.

The new Carnegie Physics Laboratory at University College, Dundee, Scotland, has been formally opened by Sir Joseph J: Thomson, of Cambridge University.

Resignation of Professor Chandler.

Professor Charles Frederick Chandler, head of the department of chemistry at Columbia University, has tendered his resignation, after forty-seven years spent in the service of that institution.

The trustees voted to accept his resignation with regret, and provided that during the next academic year he should have leave of absence, his connection with the university to expire at the end of that time. When taking action on this matter the trustees passed the following minute:

"In receiving the application of Charles F. Chandler, Ph. D., M. D., LL. D., Sc. D. (Oxon.), Mitchill Professor of Chemistry, to be relieved of active service at the close of the present academic year the trustees wish to place on record an expression of their sincere appreciation of the distinguished service which Professor Chandler has rendered to Columbia University and to the science of chemistry during his long and active career as teacher and investigator.

"Immediately upon receiving the degree of Doctor of Philosophy from the University of Göttingen in 1856, Professor Chandler entered upon his lifework of academic teaching. From 1857 until his appointment in 1864 to be Professor of Chemistry at Columbia, Professor Chandler was head of the chemical department of Union College. On his transfer to Columbia in 1864, he threw himself heartily and generously into the task of developing the newly organized School of Mines. In addition to the heavy duties of his professorship, Professor Chandler served for thirty-three years as Dean of the School of Mines, and to his effective and conscientious administration of its business that great school owes no small share of its usefulness and prestige. Besides bearing the burden of administrative and teaching duties, Professor Chandler found time for important public service during many years' incumbency of the presidency of the Health Department of the City of New York. He has also been an enthusiastic and prolific investigator of chemical problems, particularly those arising from the application of the science of chemistry to the public health and to the various forms of industrial activity. Professor Chandler is a member of the chief learned societies, at home and abroad, in which chemists are represented, and he has received well-merited recognition at the hands of his colleagues in chemistry in England, as well as in America, together with the highest honors of the University of Oxford. The chemical museum of the university, which has been built up by his efforts and in no small part by his generosity, is unique of its kind and will remain a monument to his untiring activity.

"Professor Chandler will carry with him into his retirement the affectionate regard and esteem of two generations of students, as well as of a host of colleagues on the teaching staff of the university.

"The trustees record their grateful appreciation of this long and generous career of devoted service."

During the majority of Professor Chandler's term of service at Columbia he was identified with the School of Mines, now the School of Applied Science, and was one of the three men whose efforts made its existence a possibility in 1864. At this time he was made dean of the school and he served in this capacity until the time of his resignation in 1897. While he was at its head, the School of Mines grew from a very small department of the university to one of its largest branches. Since his retirement from the office of dean, Professor Chandler has continued his work as professor of chemistry. He has taught up to the present time and will continue to do so, until the close of the present academic year.

Professor Chandler has an enviable reputation in the realm of chemistry. He was one of the leaders in the celebration of the centennial of the discovery of oxygen, which was held at the old home of Joseph Priestley in 1874. It was at this time that the American Chemical Society was organized. In 1899 the Society of Chemical Industry honored Professor Chandler

by electing him president, the first American chemist to receive such recognition.

That the School of Mines did not seem at first a very promising project is recalled in an article in the Columbia *Alumni News*. Three professors, however, were found who were willing to begin without salaries. George T. Strong, William E. Dodge, Jr., and several others furnished about $3,000 to equip the laboratory. A fine cabinet of minerals was donated by the Hon. Gouverneur Kemble, and President Barnard, Dr. Torrey, and other trustees of the college encouraged the enterprise in every possible way. Some vacant rooms in the basement of the college were assigned for laboratories. Provision was made for twelve students, but twenty-four came the first day. The success of the School of Mines was remarkable. During the entire winter the carpenters and gasfitters were constantly at work erecting new tables for additional applicants, and the number of pupils reached forty-eight.

During the first vacation a large four-story building was placed at the disposition of the school, with funds for the equipment of laboratories and cabinets. Accommodations were arranged for seventy-two pupils. During the second year the school was thronged; eighty-nine students were in attendance. The success of the new school seemed so well assured that the trustees arranged to place it on a substantial basis as a coordinate department of the college. Professor J. S. Newberry was called to the Chair of Geology, relieving Professor Chandler of this subject, and a full faculty of professors and assistants was established. A new building was erected, and equipped with laboratory accommodations for 150 pupils.

From this time on the school continued to prosper, and was from time to time expanded by the establishment of nine courses of professional study, until it became one of the most important schools of applied science in the country and acquired an international reputation. Professor Chandler was made dean of the faculty at the beginning, and was the executive officer of the School of Mines for thirty-three years. He resigned in 1897, when the university moved to its new site. During the long period of his connection with Columbia, Professor Chandler has lectured upon all branches of chemistry—theoretical, analytical, and applied. At the present time he lectures upon general and industrial chemistry, the other branches being taught by his colleagues and assistants. During the earlier years of the School of Mines the assay department was an especial hobby of Professor Chandler, and with the aid of his successive assistants he has made it the most complete of its kind to be found anywhere. To facilitate the work of assaying gold and silver ores and to insure accuracy in calculating the results, Professor Chandler devised in 1866 the system of assay weights now in general use by all assayers.

Upon the suggestion of Professor Chandler Havemeyer Hall was provided by the Havemeyer family of New York City. Preliminary to perfecting the plans of this remarkably complete institution, Professor Chandler visited and inspected every laboratory of consequence in Europe. The chemical museum, which is the personal creation of Dr. Chandler, is the most complete [illegible] of the kind in the world, and it is unique. It gives the visitor some idea of the extent to which the affairs of man depend upon the science of chemistry.

By the resignation of Professor Chandler a serious gap is made in the instructing staff of Columbia University. A successor, and an able one, will of course be provided, but it will be difficult to find a man who will be able to act in all the capacities that Professor Chandler has served in, those of personal adviser, executive head, chemical instructor, and loyal friend.

The Iron and Steel Market.

Industry has been a dull sample in the iron and steel trade, as was December. There has been the usual mill reaction in sentiment after a prolonged advance. Not since the great boom of 1899 had the industry experienced so important an advance in prices, and never in its history has it experienced so spectacular an increase in production, since from April to December fully 10,000,000 tons was added to the annual productive rate of pig iron.

The present reaction is purely one in sentiment, and by no means touches either production or prices. It is only human nature, perhaps, to be disappointed that further good news has not come out in the industry. The sweeping nature of the improvement in the latter half of last year had the double result of leaving no reasonable room for further improvement and of discouraging men from expecting any termination to it.

As to orders, there has been a lull, relatively speaking, for two months. These are months which are customarily quiet in the industry. No large projects are undertaken at this time and there was a particular incentive for buyers to crowd all possible business into the old year, on account of the trend of prices. There was much buying and specifying on contracts at terms which cannot be duplicated.

All signs point to the current year being one of minor fluctuations in demand, production and prices. There is no room for large swings in prices. The advance, while spectacular, was moderate, since it followed a break in prices extremely low considering the advances in costs of material and labor since the historic low prices of the middle nineties. There is no room for a great break in prices, and it can scarcely be thought there is room for a runaway market, considering the great increase in productive capacity. It strained the industry in 1907 to pass a pig iron production rate of 27,000,000 tons a year, but the present productive capacity is between 31,000,000 and 32,000,000 tons and new furnaces in course of erection will add 2,000,000 tons before the year is out.

It is not likely that there will be any great changes in total demand during the year. Production was brought up to a rate of between 31,000,000 and 32,000,000 tons of pig iron a year at the close of 1909 by a demand coming chiefly from the smaller lines of consumption, the demand based upon prosperity in the agricultural sections being most conspicuous. The consumption of steel in large projects which have to be financed was relatively light. The railroads really took very little iron and steel in 1909. While the year's production of pig iron closely approached that of 1907 and exceeded that of 1906, the railroads did not take, in cars, locomotives and rails, one-half as much material as they did either in 1906 or 1907.

It is fair to assume that a considerable portion of the demand of 1909 was for the purpose of replenishing greatly depleted stocks of material in the hands of jobbers and manufacturing consumers. This might, perhaps, point to a slight decrease in their requirements in the next few months. The industry could stand the reduction and still find itself with a much greater tonnage than at its best former rate, but at the present time the consumption of iron and steel for railroad purposes is very much greater than the average of 1907. The locomotive and car shops are running almost full, and the orders now on their books represent much more business than the actual output of the entire year 1909. Current reports are that the prospects of additional railroad buying are not good, but the business already placed guarantees a better tonnage for this year than there was last year.

Iron Ore.

Late in December Lake Superior ore interests fixed prices for the season of 1910 at an advance of 50 cents a ton over the schedule for 1908 and 1909, thus restoring the prices which were held for the single season 1908, these being $5 for old range Bessemer, $4.50 for old range non-Bessemer, $4.75 for Mesabi Bessemer and $4 for Mesabi non-Bessemer, all at lower lake ports, basis guaranteed 55 per cent iron (natural state) for Bessemer ores and 51.50 per cent for non-Bessemer ores. Consumers had already made large reservations of ore, particularly of Bessemer, pending the decision as to prices, and these reser-

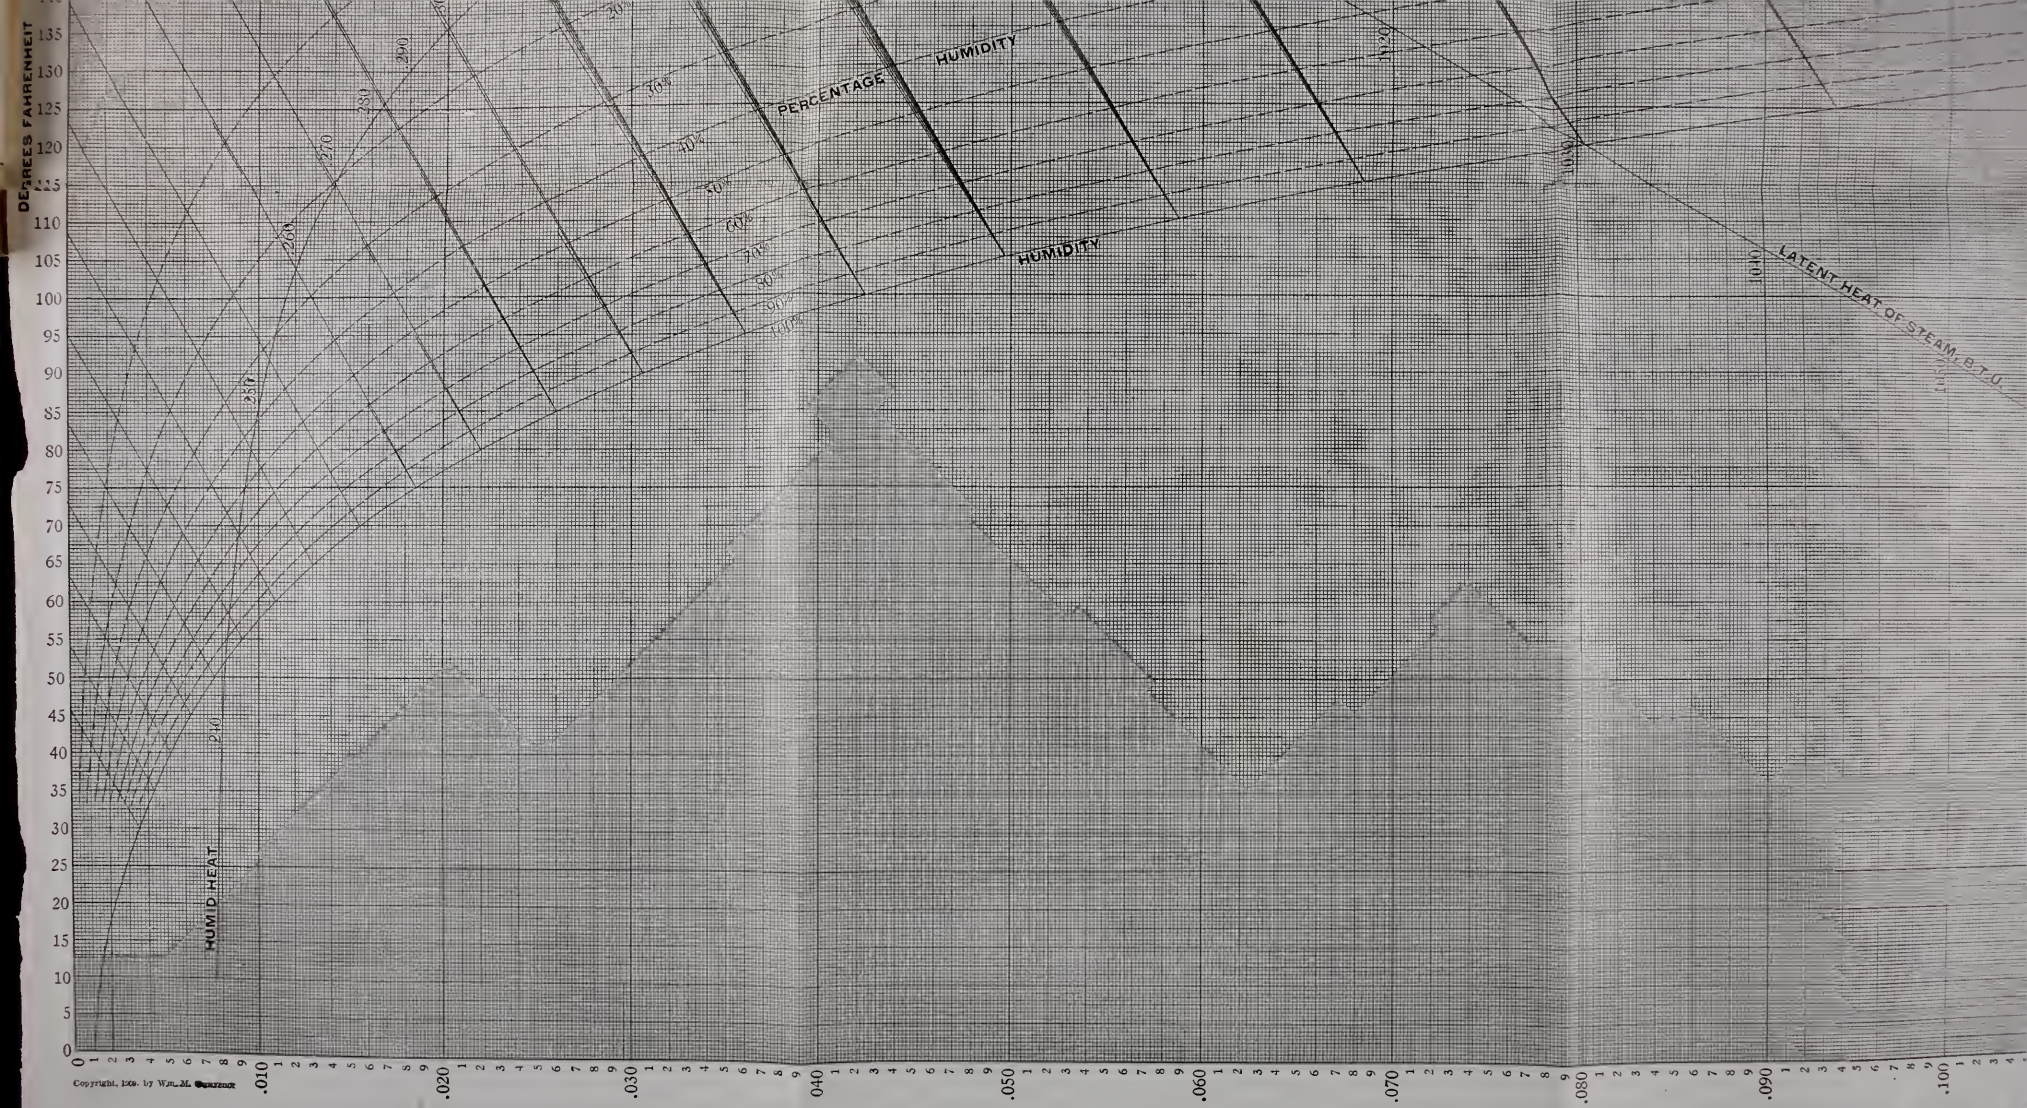

CHART I: HUMIDITY

vations were promptly converted into actual purchases. By the middle of January more ore had been sold than in any previous year at the date. All the merchant Bessemer ore that will be brought down has been sold, and by far the major part of the non-Bessemer. A feature of the buying was that three independent steel interests, normally self supporting in ore, bought a total of about 750,000 tons of merchant ore, their purchases in previous years having been very light.

The present ore prices have not been equaled since the opening of the Mesabi range, except in 1907, but a conspicuous difference in conditions is that pig iron is from $4 to $5 a ton lower than it was when the heavy buying was done for the season of 1907. By so much has the relation between Lake Superior ore and the pig iron which is made from it changed in three years.

Vessel rates from upper lake ports to Lake Erie ports were advanced five cents from the 1909 basis, to 70 cents from Duluth, 65 cents from Marquette, and 55 cents from Escanaba. At the same time the Lake Erie docks reduced the unloading charge, which is paid by the vessels, from 20 to 15 cents, so that the vessels are in 10 cents a ton better position than last year.

Other transport charges on Lake Superior ore are unchanged. The rate from the Mesabi range to docks at the head of the lakes remains at 80 cents, this including the dockage, and this with the 70 cent vessel rate makes a total cost of $1.50 delivered through Lake Erie docks. The rail freight from Lake Erie is 56 cents to the Mahoning and Shenango valleys and 98 cents to Pittsburgh, making the total transport charge from Mesabi mine to Pittsburgh furnace $2.48, covering a distance of more than a thousand miles. The traffic, nevertheless, is quite profitable. The statement is generally credited that there is more than 40 cents profit to the Minnesota ore roads, while Lake transportation must be fairly profitable or ore interests would not have been building lake vessels in the past few years, while the rail rates at the lower end are admittedly quite satisfactory to the railroads.

Pig Iron.

Southern iron has experienced a fairly good movement in January, prices undergoing no change. In a limited way iron can be bought on the basis of $13.75, Birmingham, for No. 2 foundry, if for immediate shipment, while $14 is given for extended delivery, to July 1 and probably through third quarter. The Philadelphia market has shown a fair turnover in basic, at $18.75, delivered eastern Pennsylvania. The valley market is practically unchanged as to prices, although the tone became easier during the month. Basic and No. 2 foundry are available at $17, valley furnaces, for first quarter, and at $17.25 for extended delivery. Bessemer remains firm at $19, valley, although quiet. Buffalo has shown the lowest prices at northern furnace, $17 being shaded rather freely.

Steel.

The tone of the unfinished steel market has been slightly easier. Sheet bars are available at $29, maker's mill, Pittsburgh or Youngstown, for extended delivery, and occasionally odd lots are offered at a slight concession. Billets may be roundly quoted at $27.50 for Bessemer and $28 for open-hearth, Pittsburgh. Wire rods are very quiet at $33, Pittsburgh. A comparatively easy market for unfinished steel is to be expected, as the pressure for delivery of finished material is not equally distributed among the different finished lines.

Finished Materials.

There has been no definite trend in prices of finished steel products. Merchant steel bars, which were available in December in a limited way at $1.45, Pittsburgh, although the general market was more fairly quotable at $1.50, have been firmly on the basis of $1.50 since the first of the year. Hoops are likewise slightly higher, being quotable at $1.60 to $1.65. Other finished steel products are unchanged. The market is quotable as follows, at Pittsburgh unless otherwise noted:

Standard steel rails, $28 for Bessemer, $30 for open-hearth, f.o.b. mill, except Colorado; light rails, 40 and 45-pound, $27.

Plates, $1.55 for tank quality, ¼-in. and heavier.

Shapes, $1.55 for beams and channels, 15-in. and under, zees and angles 2 x 3 and larger.

Steel bars, $1.50, base.

Iron bars, $1.65, Pittsburgh; $1.60, Philadelphia; $1.55 to $1.60, Chicago.

Wire nails, $1.85, base; plain wire, $1,.65; galvanized barb wire, $2.15.

Black sheets, 28 gage, $2.40; galvanized, $3.50; blue annealed, 10 gage, $1.90; painted corrugated roofing, $1.70 per square; galvanized, $3.

Tin plates, $3.60 for 100-lb. cokes.

CORRESPONDENCE.

Silundum.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—In your issue of December, 1909, in which is contained the report of the meeting of the American Electrochemical Society, I find the paper on "Silundum," by Prof. S. A. Tucker, and I regret to say that I am incorrectly reported as follows: "Dr. Acheson remarked that silundum was nothing new; it was the same product that he had called siloxicon." So near as I now remember what occurred was as follows: The president invited me to open the discussion following the reading of Professor Tucker's paper and I made these remarks: "Mr. President, you will kindly excuse me from entering into a discussion of this matter. From what I had formerly heard regarding silundum I was under the impression that it was a compound of carbon, silicon and oxygen, and was, therefore, the compound which I have designated as siloxicon. Since hearing the reading of Professor Tucker's paper, I now appreciate the fact that there is no oxygen present."

My reason for asking to be excused from entering into a discussion of the product as produced by Mr. Bölling was due to the fact that Mr. Bölling was formerly my assistant, he having entered my employ, I believe, in the latter part of the year 1893, while I was still at Monongahela City, and he went with me to Europe as assistant engineer in 1894, and I returned to this country leaving him abroad.

In the active zone of the furnace, as I understand it is operated by Mr. Bölling, there are three elements which may react on each other, viz., carbon, silicon and oxygen. In analyzing the possible reactions and the products that might be obtained from these three elements we find that the furnace content may be so proportioned and the furnace so operated as to produce either graphite, metallic silicon, carborundum, or amorphous carbide of silicon (as made by P. Schützenberger and described by him in a communication to the Academy of Science of France, May 16, 1892), or we may have all the three elements so associated as to produce siloxicon. As to the possibility of any other product being made, I am not advised, but the foregoing were old before the world was informed of Mr. Bölling's experiments.

NIAGARA FALLS, N. Y. E. G. ACHESON.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—In the December issue, 1909, I find an account of an American Electrochemical Society paper on silundum by Prof. S. A. Tucker, H. F. Kudlich, and E. M. Heumann, and in the discussion of this paper a statement of Dr. Acheson that silundum was nothing new; that it was the same product which he had called silixicon.

I must contradict Dr. Acheson and I claim the priority of the discovery of this new material and of the fact that silicon vapors penetrate into carbon, when both are in a highly heated state, converting the carbon into a refractory, electrically conducting material, of a composition with varying proportions of

silicon and carbon. Silundum, therefore, as described in my paper, published in this journal, January, 1909, in form of rods, tubes, crucibles, or any other shape made of carbon, is new. The date of my first German patent is April 24, 1904, and I started experimenting October 31, 1903.

Silundum is used now in Europe for various purposes, especially for electric heating purposes. It is manufactured by the Chemisch Elektrische Fabrik Prometheus in Frankfurt.

Oberwesel, near Frankfort, Germany. F. Bölling.

Iron-Copper Alloys.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I have read with considerable interest the abstract of Charles F. Burgess' and James Aston's paper on "Iron-Copper Alloys," published in your December issue (Vol. VII, page 527), and believe that the following points are of sufficient importance to bring to the attention of your readers. In the preface the following statement is made:

"The influence which copper has in iron and steel has for long been a subject of controversy and contradiction. It is only comparatively recently that the effect has been investigated systematically and some of the doubt eliminated.

"The prevalence of appreciable quantities of copper in the ores of certain districts makes important a knowledge of its effect, detrimental or otherwise, when present in small amounts. Also the intimate relation of copper, nickel and iron, and the beneficial effect of the addition of nickel to iron and steel, creates an interest in the influence of larger percentages.

"The older opinion was that copper was deleterious; that its chief effect was analogous to that of sulphur in that it rendered iron red short and destroyed its welding power. This view was taken by many eminent metallurgists, some even contending that 0.5 per cent makes steel worthless. Others claimed that the influence was greatly exaggerated, and instances were cited where rolled sections of 0.50 per cent to 0.75 per cent of copper did not display red shortness."

With this statement, the authors proceed to manufacture the alloys, using pure iron and pure electrolytic copper, and while the abstract of the paper does not so state, I judge that the alloys were made from these materials, using the crucible to melt the same. In the manufacture of crucible steel the base materials are melting bar which is obtained by puddling, rolling and rerolling; blister bar obtained by carbonizing the melting bar, and "medicine." This latter consists of black oxide of manganese, clay and any of the ferro-alloys which may be required to produce the kind of steel.

The base material in the crucible manufacture is, therefore, practically wrought iron, which would be free from any copper that might have been contained in the ore from which it came. The puddling and reworking operations would have completely eliminated the copper with the slag, so that it is quite safe to say that no crucible steel contains copper except that intentionally added or introduced with the alloys. Furthermore, crucible steel is the highest grade of steel and is made from selected bar iron, which is usually made from the highest grade of ores and these are free from copper.

These base materials are charged into a pot and protected from the air by a cover and the slag, so that the steel is made in practically a closed receptacle away from all oxidizing influences. Therefore, the resulting product is quite free from all oxides and therein to a large measure lies the superiority of the crucible steel. It would follow that the alloys manufactured by the authors would be the freest from oxides, and have been produced by a process which is never used in the manufacture of steels in which copper from the ores is likely to be found.

The writer believes that the oxide or suboxide of copper is the real cause of the red shortness which is characteristic of the steels containing copper, and all of such steels are the product of the open-hearth or Bessemer processes. In both these processes there is every chance for the formation of an oxide of copper since these steels contain, in comparison to the crucible steel, considerable quantities of the oxide of iron, silicates, etc.

The quantity of the oxide is largely dependent upon the composition of the steel; for instance, that steel low in carbon and manganese is usually found to contain more oxides since the oxidizing action has been carried to a greater degree. Furthermore, the steel made in the basic open-hearth furnace usually contains more oxide than acid open-hearth steel. In the latter process the basic oxides combine with the acid slag and are more readily eliminated from the steel.

Hence, it follows that the amount of copper permissible in open-hearth or Bessemer steel, without the production of red shortness, is of variable amount depending upon the composition of the steel, the degree to which it has been subjected to an oxidizing reaction, and the degree to which the oxides formed by the oxidizing reaction have been eliminated from the steel.

In other words, the degree of red shortness produced by the presence of the copper is dependent upon the conditions of the

HOT ROLLED STEEL.

manufacture and the other elements in the steel. My experience has shown that when the carbon and manganese are low (carbon less than 0.10 per cent, manganese less than 0.12 per cent) the presence of 0.5 per cent of copper produced a decided red shortness. The photographs of some hot rolled steel, herewith reproduced, speak for themselves, showing how the material acted under the rolls. That on the right is higher in manganese by 0.06 per cent and contains less copper. It rolled out very well, showing no red shortness. That on the left is higher in copper and lower in manganese. It showed decided red shortness, as the photograph indicates.

The paper by Messrs. Burgess and Aston is a very good one and quite interesting, but the preface does not seem to me to be quite in harmony with the work which they have done. The two together give an erroneous impression, and the comment made by Dr. J. W. Richards in the discussion (that much of our steel contains copper, from 0.5 to 0.7, that it has been claimed privately that the copper is not injurious, but rather beneficial and that this has now been established by Professor Burgess) would seem to me had been made while under the influence of this wrong impression.

I trust that I have made my remarks sufficiently clear so that the points, which I wish in particular to bring out, will be considered.

Reading, Pa. Geo. W. Sargent,
Metallurgist Carpenter Steel Company.

The Presentation of the Perkin Medal to Dr. E. G. Acheson.

At the meeting of the New York Section of the Society of Chemical Industry, held at the Chemists' Club on Friday, Jan. 21, the Perkin medal was presented to Dr. EDWARD GOODRICH ACHESON, of Niagara Falls. In spite of the inclement weather the meeting was well attended, not only by members of the Society of Chemical Industry, but also by members of the American Chemical Society and of the American Electrochemical Society, Dr. Acheson being a past-president of the latter society.

Mr. MAXIMILIAN TOCH, as chairman of the New York Section of the Society of Chemical Industry, referred in his introductory remarks to the presence of so many who had come from a distance to attend this meeting, and said that "it is seldom given to any man that, when his work is successfully crowned, it be done in the presence of so many prominent scientists. We are assembled to-night to do honor to our fellow-member, Dr. Edward Goodrich Acheson, to present to him the Perkin medal, which originated practically in this hall four years ago. It will always be a credit to the Society of Chemical Industry that the first Perkin medal was presented to Sir William Henry Perkin himself, and many a brilliant gathering has taken place here, but none more brilliant than that at which we are assembled."

Mr. Toch also said that "although Dr. Acheson's name has been linked for many years with the invention of artificial graphite and carborundum, still those of us who have watched his scientific career more closely have, like myself, been most interested in the work he has done in colloid chemistry."

Mr. Toch then called upon Dr. Charles F. Chandler to present the Perkin medal to Dr. Acheson.

E. G. Acheson

Address of Presentation.

Dr. C. F. CHANDLER spoke as follows:

"It is my pleasant duty, as the senior past-president of the Society of Chemical Industry in this country, to present to Dr. Edward Goodrich Acheson the fourth impression of the Perkin medal.

"Dr. Acheson possesses the rare merit of combining the inventive, the constructive and the organizing faculties. He has been most successful in discovering entirely new materials suitable for a great variety of purposes which have become indispensable to the world. He has also been able to devise the most perfect methods and appliances for producing his new products on a large scale, and he has been able to organize and finance great companies to put his inventions into successful operation."

Dr. Chandler outlined briefly the early life of Dr. Acheson (see our Vol. I, page 90), and then spoke at greater length on the chief inventions of Dr. Acheson, as follows:

"Carborundum."—In 1886, while making some experiments, he passed a quantity of hydro-carbon gas over highly heated clay and observed that the clay became impregnated with carbon. In the early part of the year 1891, having at his command an electric generating plant of considerable capacity and looking about for a line of experiments, he thought to try the impregnating of clay with carbon under electric heat. The mass resulting from the experiment exhibited a few small crystalline specks. These he carefully examined and found that they not only scratched, but actually cut glass. They appeared like minute gems. Grasping the possible value of his discovery, he undertook further experiments and after two months' labor succeeded in obtaining a few grams of crystals. In order to test their value as an abrasive, he mounted an iron disk in a lathe, charged its surface with his new unknown product and found that this revolving disk cut the polished face off a diamond.

"Having satisfied himself of the abrasive quality of his new product he took it to a diamond cutter in New York, who tested it, and was glad to buy it at 30 cents per karat; and with the proceeds of this first sale Acheson purchased a microscope to assist in the further study of the material. Having thus obtained this material from clay and carbon, and not yet knowing its chemical composition, he gave it the new name 'carborundum,' but he soon learned that it was the silicon of the clay, and not the alumina, which united with the carbon, producing a carbide of silicon, but the name 'carborundum' has been retained for the substance ever since.

"In 1894 he established the Carborundum Company at Monongahela City, Pa., but subsequently moved to Niagara Falls, where he finally erected works and equipped a plant with 5000 electric horse-power and where he has manufactured more than 7,000,000 lb. of carborundum.

"Time will not permit me to enumerate the various uses to which this new abrasive substance was applied. Suffice it to say that nearly 600 men are employed in the works at Niagara Falls in preparing carborundum and fashioning it into wheels, sharpening stones, hones, bricks, knife sharpeners, paper, cloth, etc., fitting it for every kind of abrasive application. I should not omit to say that carborundum has proved a special substitute for ferro-silicon in the manufacture of steel.

"Artificial Graphite."—In the carborundum furnace Acheson noticed that in the hottest zone, next to the carbon core, there was produced between the core and the carborundum crystals a thin layer of graphite, which he decided must be produced by the dissociation of a portion of the carborundum and the expulsion of its silicon in vapor. The discovery led Acheson to make a long series of experiments, the result of which was the discovery of a process for converting amorphous carbon, such as coke or anthracite, into beautiful artificial graphite. As a result the International Acheson Graphite Company was organized and large works were erected for the manufacture of artificial graphite. This company turns out several million pounds of what is termed bulk graphite made principally from anthracite coal.

"Graphitized Electrodes."—In addition to the bulk graphite, shapes suitable for electrodes are prepared, and by subsequent exposure to the proper heat in the electric furnace, they are converted into graphite, hard and compact. These graphitized electrodes have proved of the utmost value in various electrolytic operations, as they are found to be many times more suitable than the carbon electrodes previously used. The company manufactures several million pounds of these graphitized electrodes annually.

"Soft Graphite."—The artificial graphite produced by the International Acheson Graphite Company was hard and well suited for use as electrodes for electric furnaces and electrolytic cells and for many other purposes. In 1906 Mr. Acheson devised a process for producing a soft graphite. This graphite is especially valuable for use as a lubricant, a stove polisher, coating electrotype molds, etc. This graphite is not only pure and soft, but unctuous, and does not coalesce when compressed.

"Deflocculated Graphite."—In investigating different clays in connection with the manufacture of artificial graphite crucibles Mr. Acheson's attention was called to the great difference in the plasticity of various clays, and especially to the fact that clays far removed from their place of origin were most plastic,

and the idea came to him that this might be due to the fact that in their transportation by water they had become impregnated with vegetable extracts which might increase their plasticity. With this idea in mind, he conducted a series of experiments with various clays and discovered that by treatment with tannin the soft graphite is so modified that it remains suspended indefinitely both in water and in oil, and he immediately realized the importance of the discovery, as enabling him to supply the world with a new lubricating agent invaluable in all purposes where lubricants are required. The value of this discovery is best shown by the fact that a shaft can be run from 50 per cent to 100 per cent faster with oil containing deflocculated graphite than with the plain oil.

"Siloxicon.—In the latter part of the summer of 1893 Acheson became interested in the direct reduction of silicon, and among other experiments he mixed graphite and silica, and exposed the same to the electric current with a view of producing silicon. He produced in this way a peculiar product which he found to be highly refractory. Analysis showed it to be composed of silicon, carbon, and oxygen, hence the name siloxicon. A special company was organized for the manufacture of this interesting product and for producing from it such articles as crucibles, muffles, bricks, etc.

"It is impossible in the short time allotted to me to give anything like an adequate account of all of Dr. Acheson's achievements. Nor it is even possible to give a full account of any one of them. But I have said enough to make it clear that Dr. Acheson is an inventor of the first order—a thorough electrician and a thorough chemist. His efforts have not been directed merely to improving processes and products previously known. He has made entirely new departures and created new industries, supplied previously unknown materials for use in the arts and industries, and he has discovered uses for his new materials and processes for their application. He is a representative electrochemical engineer, and it is eminently proper that he should have been selected by the great chemical societies of this country to receive the Perkin medal.

"It gives me great pleasure, Dr. Acheson, as the representative of the Society of Chemical Industry and the affiliated chemical and electrochemical societies, to place in your hands this beautiful token of the appreciation and affection of your fellow-chemists."

The Dawn of an Electrochemical Epoch.

Dr. E. G. Acheson replied as follows:

"It was a coincidence of more than ordinary importance to me that I first saw the light of this world in the spring of 1856—the very year made memorable by the great discovery of the dye stuff 'mauve' by Sir William Perkin. During my childhood and early manhood occurred the development of most of the great chemical and metallurgical industries with which we are now so familiar.

"In the last quarter of the nineteenth century the world was ready for another step forward in the chemical arts. It was ripe for the birth of a new industrial chemistry, until then unknown—industrial electrochemistry. I believe this birth occurred at the time of Hall's work on aluminium. The great movement for the conservation of our natural resources calls into action a vast amount of work that properly will fall to the chemists of all kind of industries, especially the electrochemists. Their field of research and development will be practically limitless and will extend beyond what the world is now considering the conservation of natural resources, for they will create valuable products from matter now classed by the title of refuse—a field largely devoted to synthetic work.

"I wish to thank you and the societies which you represent, Mr. ——, for the great honor you have conferred upon me, and I have no greater or more sincere desire than that my work may, in a small way, stimulate the rapid expansion and development of synthetic electrochemistry which will result in a great electrochemical epoch, following the chemical era brought to life by the illustrious scientist in whose honor this medal was created."

Dr. Acheson then entered into a description of some of his more recent work on deflocculated graphite, aquadag and oildag. He spoke in an informal way and illustrated his remarks by exhibits and various experiments. It was exceedingly interesting to follow in detail the various steps of discovery, speculation, and invention by which Dr. Acheson finally realized what he prefers to call "deflocculated graphite," or graphite in the colloidal state.

A Classic for Children and an Inspiration to Chemists.

Dr. Wilder D. Bancroft, of Cornell University, then spoke as president of the American Chemical Society, as follows:

"On an occasion like this it is an honor to represent anything. It is a great honor to represent the American Chemical Society. There is a personal reason why it is an especial pleasure to me to be one of the speakers on the particular evening on which the Perkin medal is awarded to Mr. Acheson.

Most of you can remember the time when physical chemistry was looked upon as a fad, interesting enough, but purely theoretical. Some of us preached in season and out of season that a proper training in physical chemistry was the ideal training for an industrial chemist. We were looked upon as harmless maniacs and consequently were not ill-treated. It did not do any good for us to talk like that unless we could prove it—and there was always the painful possibility that we might be wrong.

"I do not wish to claim for Mr. Acheson that he was the first manufacturer to employ a physical chemist at a good salary. I am always hazy on the subject of dates, but I imagine that that honor belongs to the General Electric Company. Mr. Acheson was the first manufacturer, however, who was rash enough to try the Cornell product.

"Once the ice was broken everything went well. So far as I know, the properly trained physical chemist has always made good in industrial work. You remember the French proverb 'Ce n'est que le premier pas qui coute,' which may be rendered into the vernacular as 'It is only the first year that you don't earn your salary.'

"A man who receives the Perkin medal is expected to have made several great inventions. That has been the case so far, and, from what I know of American chemists, the supply is likely to hold out for many years to come. There is a great difference in the work of different inventors when considered as an artistic whole. From a pictorial point of view their inventions may often be said to be spotty; they are determined by business exigencies, or they are like lightning, which is said never to strike twice in the same place. I have never tried the experiment.

"Take our friend Backeland, for instance. He is after me tonight, but I am after him now. He has made two great inventions. Velox is one and bakelite is the other. There is no visible connection between them, and there is no fundamental reason why they should have been made by the same man. They are individual outbursts of genius.

"Take the first man to whom the Perkin medal was awarded, Mr. Herreshoff. I remember that Dr. Chandler cited as two of his inventions improvements in the series system for refining copper electrolytically and improvements in the contact process for making sulphuric acid. Copper sulphate is the electrolyte used in the electrolytic refining of copper and it is made from sulphuric acid, but these are really separate inventions. So far as I can see the only thing which they have in common or which holds them in common is the General Chemical Company.

"If we do not limit ourselves to the field of chemistry everybody will admit that Mr. Edison is the greatest of American inventors. He converted electrical energy into light in the case of the incandescent lamp, he converted electrical energy into sound in the case of the phonograph or gramophone, whichever it was that he invented, he converted chemical energy into

electricity in the case of his storage cell. These inventions hang together in a very satisfactory way; but how are you going to fit in his invention of monolithic cement houses for the poor?

"In the case of Mr. Acheson there is a logical sequence about his inventions which delights the soul of any one like myself who lectures on applied electrochemistry. Mr. Acheson invented carborundum. The carbon in the cone of the furnace changed partially to graphite and he worked out a method for preparing graphite on a commercial scale. On the outside of the carborundum layer there was a ring of 'white stuff' as it was called, and Mr. Acheson organized a company to manufacture siloxicon. There were lumps of silicon throughout the carborundum and a former assistant of Mr. Acheson, Mr. Tone, worked out a process for making silicon, thereby giving the commercial world a new element. Everything in the carborundum furnace has been worked into an industry with the exception of the unchanged charge and that they use over again, so that it is not wasted.

"If Mr. Acheson will forgive me for slurring over the distinction between discovery and invention, I should call him the Swiss Family Robinson of chemistry. You remember the book. The shipwrecked family went out to search for food, and they discovered a bread-fruit tree with sandwiches growing on it. They came to a stream and they invented a cantilever bridge which they constructed with the aid of a bow and arrow and a dog. They discovered or invented a palm tree with cocoanuts growing at the top. In order to get the cocoanuts they invented or discovered a shark stranded in the shallows; they made gaiters of his skin and climbed the tree. Now nature had intended the cocoanuts to be blown off the tree, and when they were brought down by hand it at once became a problem how to open them. Our friends thereupon discovered or invented a crab which inserted the points of its claws in the holes of the cocoanut and spun a yarn which broke the shell and enabled them to get the milk in the cocoanut.

"The analogy with the work of Mr. Acheson is obvious. He began by trying to make diamonds. He denies this, but the myth persists in spite of him. When the crucible was opened there were no diamonds but instead a mass of multi-colored jewels. When he discovered that they were not real gems it was a crushing blow and so hard that he decided to use them as an abrasive. To make carborundum he needed electrodes, so he invented graphite. A suitable refractory was needed to keep the heat in the furnace, and Mr. Acheson thereupon prepared siloxicon. The furnace had to have brick walls at first, and they were promptly forthcoming in the form of Egyptianized clay. In order to keep everything running smoothly, including the three automobiles which he had acquired in the meantime, Mr. Acheson prepared the lubricating graphite which he has shown you to-night as aquadag and oildag.

"When you stop to think of him, Mr. Acheson's work is really a classic for children as well as an inspiration to chemists. He has revolutionized many branches of chemistry and he has revolutionized the whole of electrochemistry. I should like to say a good deal more about this last, but I should play havoc with Baekeland's typewritten speech if I did.

"You may consider Acheson's discoveries as scientific inventions or as dividend payers; you may even look at them in a flippant way. It makes no difference. They stand all tests and they stamp him as one of the great inventors of the world.

"I am speaking to-night for the members of the American Chemical Society, forty-five hundred strong at Christmas, and probably five thousand now unless Parsons has been taking a vacation. In the name of the American Chemical Society I congratulate you, Mr. Acheson, upon the honor which you have received to-night and which you have so richly deserved."

Pathfinder, Conductor, Switchman—Everything.

The last address of the evening was made by Dr. L. H. Baekeland, as president of the American Electrochemical Society. Dr. Baekeland said:

"What is more to the credit of Dr. Acheson than anything else is the fact that he undertook experiments which probably had been attempted several times before without success by people who had more theoretical preparation than he. But his unusual keenness of observation, his commonsense logic, and more than anything, his appreciation of what was of preponderant importance and of secondary interest, brought him results where others had failed and by which he opened a new field of chemical investigation and industrial applications.

"Dr. Acheson stands as a living example to many a chemist, loaded with theoretical knowledge and paper wisdom and light in judgment or common sense. He entered into a new road with very little knowledge to go by, but he had an open mind, a fertile brain, a constructive purpose, and all the talents of the tireless, intelligent experimenter; his theoretical knowledge he made himself, or picked it up by and by along the road he was pursuing, while he himself was building that road. Whatever he took up, he started from the very beginning and developed it to the very end.

"His very insuccesses he turned into practical channels, to change them into victories. He started his work on carborundum by an experiment so simple and so meager in results that few people, if any, would, like himself, have found in this a spur to further investigation. Later on, when in the manufacture of carborundum, he had to battle with irregularities due to a partial dissociation of the silicon carbide, which thus spoiled his product, he tried by a more powerful action of heat to carry this dissociation to the extreme limit; he so created a new industry, the manufacture of artificial graphite. In the same way he turned irregularities due to oxidation or partial reduction into a new field of study and research and gave us siloxicon, a product which seems to have a considerable future in store.

"I shall not attempt to describe here the history of the work of Dr. Acheson. He himself, in a memorable address delivered in Boston before the American Academy of Arts and Sciences, when the Rumford Medal was awarded to him, has given us a most fascinating account of this subject, and to those of my fellow chemists who have not read his 'Seventeen Years of Experimental Research,' I can recommend it as an inspiration.

"Never did the University of Pittsburgh award an 'honoris causa' degree to a more worthy man than when the doctor's degree was conferred upon our distinguished friend.

"In the making of the great road of industrial progress, very few of us are path-finders; some are surveyors, other ones constructors, others, again, are merely switchmen, brakemen and conductors. Dr. Acheson not only was a path-finder, but he has been constructor, conductor, switchman—everything. By his manifold abilities and good judgment he has been able to develop his discoveries to the point where they became a commercial success. He has shown us that an inventor or a scientist does not have, necessarily, to be a theoretical dreamer, unfit for executive or practical work.

'Dr. Acheson has another great claim of recognition upon us; successful as he has been in his enterprises built on the result of his inventive genius, he has never ceased to make us feel that he was near to every one of us. He always taken an active part in the work of our chemical societies, where his presence and his papers have stimulated many of us younger in experience or less successful in our efforts. In many instances he has allowed our chemical societies to inspect the plants where his industrial processes are carried out, and he has never hesitated to publish the results of his research work. He has thus set a praiseworthy example to such of our manufacturers who try to insure by uncompromising secrecy and seclusion the money-making end of their enterprise.

"Dr. Acheson, in the name of the American Electrochemical Society, I congratulate you on this recognition of your splendid work, and I congratulate the Perkin Medal Committee just as much in their choice of you."

All speakers were applauded with considerable enthusiasm.

Treatment of Ore Slime.*

By Andrew F. Crosse.

The chief difficulty in treating slimy material with a cyanide solution is the difficulty of removing and obtaining the dissolved gold, or silver, from the slime. Many methods have been tried, and the methods chiefly in use to-day are the well-known decantation process and various filter-press processes. The decantation is very slow, and, therefore, requires an enormous plant, and a very large quantity of solution has to be handled in proportion to the weight of slime treated.

The filter-press method has many advantages, but it requires much handling and constant renewals. In my process the slime, having been collected in a suitable manner, is washed with a weak cyanide solution into a conical treatment vat. This vat is provided with an interior conical baffle, open at the bottom, and reaching about half way down the treatment vat. Inside the vat is a pipe extending, from nearly the bottom of the cone, to a foot or two above the surface of the pulp. This pipe has a small pipe introduced at the lower end, through which air is forced, this causes a current of concentrated or thickened pulp to be forced up the tube. At the same time the clear liquid, in the outer portion of the conical vat, is overflowing into the zinc box where the gold and silver are deposited, and then this clear solution, deprived of its gold and silver, is pumped by a small pump, which can be regulated as to speed, back into the top of the inside cone, where it mixes with the underflow brought up by the air-lift pump.

By this means the whole mass is kept in continuous circulation under the most advantageous condition for the solution of the gold or silver. As the air circulates and aerates the pulp, the gold and silver are being continually extracted from the solution. The same solution acts as a wash, practically all the gold and silver having been extracted and deposited in the zinc box. During the working of the process it is very easy to control the strength of the cyanide solution or the alkalinity, and should either be found too low more cyanide or alkali can be added.

Clear solution containing gold is passing through zinc boxes and depositing its gold in every cyanide plant. The circulation of cyanide solution and slime by means of an airlift pump is quite the ideal method of solution, as I have proved in hundreds of trials. Most gold ores produce on crushing a certain proportion of real slime, which is usually a hydrated silicate of alumina with an excess of silica, or a very finely divided hydrate of ferric oxide and finely ground pyrites.

Metallurgists all recognize to-day that no hydro-metallurgical gold treatment can be successful unless the ore has been sufficiently finely crushed in order to render every particle of gold or silver accessible to the solvent action of the cyanide solution. In order to carry this out tube mills, pans and other devices have been introduced, so that a large proportion of the crushed ore cannot be treated by percolation.

In my scheme I can handle any fine material, and I can treat successfully either ordinary argillaceous slime, fine sand, or finely ground pyrites. I have treated a highly ferruginous slime and obtained an extraction of 91 per cent of the gold contents from slime containing 7 dwt. fine gold per short ton. This means that the gold so obtained was precipitated in the zinc. The same slime was treated by a filter press plant, and only gave extraction of 61 per cent of the gold; this was owing to the nature of the slime as it contained so much ferric hydrate, and it was impossible to wash out the dissolved gold from the pressed slime.

The cost of erecting a plant according to my plan would be very much less than any other that I know of, as it merely requires the ordinary conical vats, pipes for air-lift pumps, zinc boxes, and an air compressor. The mechanical efficiency of an air-lift pump is quite equal to other pumps for slime pulp as the proportion submerged is very large in proportion to the actual lift required. Very little labor is required to run the plant and one attendant could look after several vats.

As regards the strength of the cyanide solution and consumption of chemicals, that would depend on the nature of the ore and would be neither more nor less than that required by other methods.

My plant (see Fig. 1) consists essentially of a conical vat *A* having within a cone-shaped baffle *B* and a pipe *C*, up which a jet of air is directed from the small pipe *D*; a further pipe *E* leads from near the top of the vat *A* into the zinc precipitating box *F*, which is provided with a pipe *G*, through which a small air-lift pump *H* returns the liquor from the zinc box to the inside of the baffle *B*.

The method of operating the plant is as follows: The slime, having been collected by any suitable method and the excess of

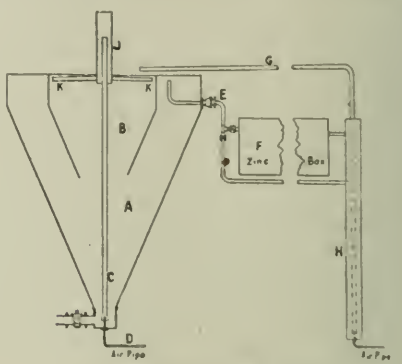

FIG. 1.—SLIME FILTRATION PLANT.

water decanted off, is washed by means of a weak cyanide solution into the treatment vat *A* through the baffle *B*. Further weak cyanide solution is then added and air turned on through the pipe *D*. This forces up through the pipe *C* into the receiver *J* a mixture of slime, dilute cyanide, and air to a point a foot or two above the level of the liquor in the vat *A*, to which it returns through the pipes *K*, which are so arranged as to give their discharge a circular motion within the baffle cone *B*.

The slime then settles down continuously, reaching the bottom of the cone in the form of a thickened pulp, and is again lifted through the pipe *C*. The pulp occupying the space between the baffle cone and the wall of the cone *A* is in a state of comparative quiescence, the only movement being a gentle flow upward of the enriched solution to the pipe *E* on its way to the zinc box. The conical shape of the vat *A* reduces the rate of upward flow and insures that the top few inches of liquor are clear and free from slime, and thus are in a fit state for precipitation. The solution deposits its gold content in the zinc box and is then returned by the pump *H* to the inside of the baffle, where it continues its work, and the sequence above described is allowed to proceed until a large proportion of the gold has been precipitated.

Having described my slime process, I would now like to go into further details.

I have made a considerable number of experiments as to replacement of the solution when the pulp is being agitated in the conical vat as described. The method I used was to have a weak chloride of sodium solution and no cyanide. I found that with the vat constructed as shown in the diagram and having a pulp containing 40 per cent of dry slime, or 1/5, I could obtain a clear overflow of 18 per cent of the contents of the conical vat per hour, and that when a volume of solution equal to the solution in the vat had been replaced by water running into the

* A paper presented at the annual general meeting held in November, 1910, of Johannesburg Transvaal Institute of the Chemical, Metallurgical and Mining Society of South Africa.

inner cone *B* that 75 per cent of the chloride of sodium had been removed. I obtained this result several times with different slimes, both in London and in the Transvaal. The same thing happens with gold and silver in solution, and as the solution, when it is returning from the zinc box, pours into the inner cone the gold-bearing solution is taken off by the decanting arm as described.

I want to call attention to one point. In beginning the operation with a solution not containing gold, the upper portion of the solution which begins to overflow would not obtain any gold for some time and it would be useless to pass it through the zinc box; therefore, in working this process I would recommend circulating for about two hours before allowing any overflow to take place. This is very easily arranged, as the pulp in the inner cone *B* is concentrated and has a much higher specific gravity than in the outer portion, the surface of the liquid is several inches below the level of the outer portion. By means of four or five 2-in. holes just below the surface of the outer portion the clear solution flows into *B*.

When this circulation has proceeded long enough the holes are plugged with wooden plugs and the clear overflow is allowed to pass through the zinc box and return to the inner cone free, or nearly free, of gold and silver. After this circulation has been started it will be apparent that at any given time the upper portion of the solution in the outer vat, between the inner and outer cone, is the richer in gold. Therefore, if the pulp be allowed to settle in the vat, the supernatant liquid is much richer than that portion in the settled pulp.

One can, if one likes, replace a strong cyanide solution by a very weak one. I treated some slime in London (from Nundydroog Mine, Mysore, India) by my process, and after seven hours' treatment the unwashed residue assayed 0.07 dwt. fine gold per ton. The original slime assayed 2.5 dwt. fine gold. This slime was slightly pyritic. There is even in slime an insoluble minimum of gold, and it would be an interesting problem for someone to find out in what condition this very finely divided gold is, and to explain why it is not soluble in cyanide solution.

It is quite evident that the capital outlay required for a plant which requires so short a time for treatment (the time for settlement must, of course, be added) is very much less than for the present plans in use on these fields. This plant is both easy and inexpensive to work. If the overflow is not absolutely clear, it will have to be passed through a clarifier of some kind; this method is usual to-day in most slime plants.

A plant has been erected on the above principle and has been working for 14 months on the Crown Mines, giving excellent results, which will be described in the paper which follows, so that it will be evident that my process has now passed the experimental stage, as a proof of which are appended some notes by Mr. Fraser Alexander on the "Treatment of Black Sands."

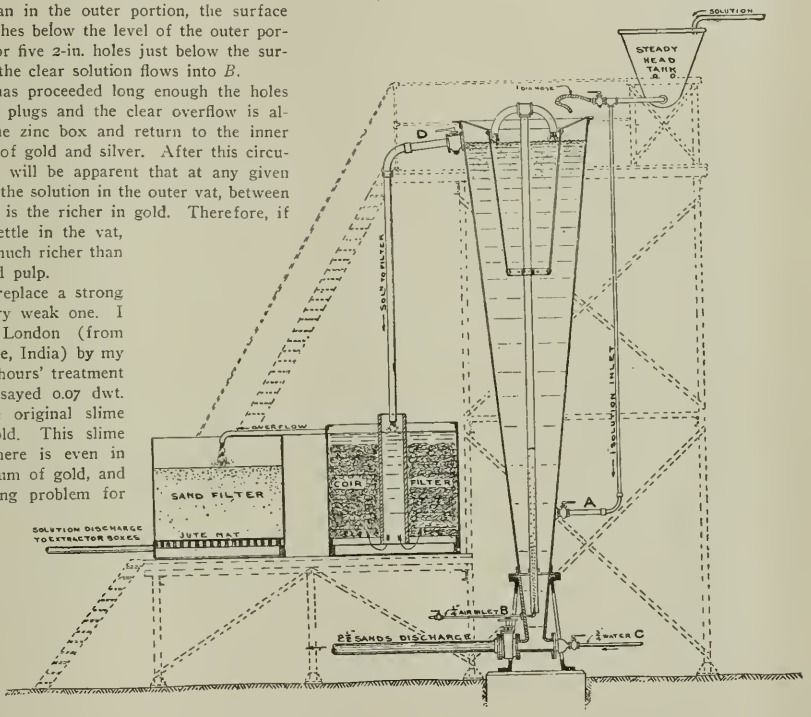

FIG. 2.—BLACK SANDS TREATMENT PLANT.

Appendum on the Treatment of Black Sands.

By Fraser Alexander.

I have been asked to explain the method of treatment and plant adopted at the Crown Mines and worked by me with considerable success since October, 1908, for the quick treatment with cyanide of our battery by-product commonly called "black sand."

After working the plant described by Mr. Burnett for a considerable period, I decided that the sampling of residues could not be relied on, and I often found amalgam accumulated immediately below the stirring gear in sufficiently large quantities to upset all calculations of actual extraction, and this was my chief objection to the paddle stirring process. Seeing a plan of Mr. Andrew F. Crosse's design for the treatment of concentrates, I decided to try the experiment on a working scale, and used for my purpose an old conical-shaped water purifier, 18 ft. deep, by 4 ft. 3 in. at the top, tapering to 2½ ft., to which I fitted air, cyanide solution, and water connections, as shown in the accompanying sectional diagram. This apparatus, which is simple in construction and costs practically nothing for maintenance, is extremely reliable and efficient for the treatment of refractory ores with cyanide.

Since installing this plant I have treated 61,340 lb. of black sands, having an average value of 23.0 oz. per ton, from which 683 oz. fine gold = 96.88 per cent and about 150 oz. of mercury were recovered. In many instances I checked the assay values of charges by sampling the solutions, from which I obtained most satisfactory results in measured quantities.

Appended is a fair specimen treatment sheet: Dry weight of charge = 500 lb. charged into the cone with ordinary working cyanide solution to which is added 15 lb. of cyanide and 10 lb. lime. Charged, 2 p. m.; circulated, 8 p. m.; started washing, 9 p. m.; rate of wash = 75 tons per hour, 3 a. m.; KCy = 0.13, CaO per cent = 0.015. Average value solution = 23.35 dwt. After further washing with weak solution (= 0.05 KCy) for six hours, the average value was reduced to 4.3 dwt. 11 a. m., solution KCy = 0.01, CaO = 0.008, Au = 0.30 dwt. Twelve noon to 1 p. m., water wash.

Original value of charge, 25.0 oz. per ton.
Value of residue = 0.51 oz. per ton.
Theoretical extraction = 97.96 per cent.

The process is practically continuous and requires very little attention.

I have no doubt that this method of treating refractory ores with cyanide is capable of considerable extension as a quick method of extracting gold and silver from their ores.

The partial analysis of a sample of treated black sands from the Crown Mines is as follows:

	Per cent.
Silica (SiO_2)	51.94
Iron, calculated as Fe_2O_3	32.62
Sulphur (S)	16.98

Assuming the sulphur to be contained as iron pyrites having a formula of FeS_2, calculation gives the following data:

	Per cent.
Silica (SiO_2)	51.94
Iron disulphide (FeS_2)	31.84
Ferric oxide (Fe_2O_3)	11.39

A qualitative investigation showed the presence of a very small quantity of arsenic, and traces of copper, titanium, cobalt, and nickel. A small amount of lime was also noted, this being a subsequent addition for treatment purposes. A negligible quantity of magnetic iron is present.

* * *

In the brief discussion which followed the above two papers and which is printed in the November issue of the *Journal of the Chemical, Metallurgical and Mining Society* of South Africa, Mr E. H Johnson said he had seen the plant in operation at the Robinson mine. The system of agitation is perfect in the central cone and gives a very clear overflow from the outer cone, but he thought that "the point in question is the amount of solution which will be required to complete the washing. In Mr Alexander's case, I do not think it is a matter of importance, owing to the high value of the original slimes."

The Late Dr. Charles B. Dudley.

It is with great regret that we record the death of Dr. Charles B. Dudley, chief chemist of the Pennsylvania Railroad, on Dec. 21, 1909, at Altoona, Pa. His loss will be keenly felt by all his colleagues in the scientific world. Not only was he very eminent in his chosen field of testing materials, but by his genial disposition, attractive personality, kindness and fairness in dealing with those associated with him, he had endeared himself to his fellow workers and members of the chemical and engineering professions. His death will be especially deplored by members of the International Association for Testing Materials, of which he was the president, his term extending until 1912.

Dr Dudley was born in Chenango County, New York, on July 14, 1842, and was educated at the local school and academy. The War of the Rebellion having broken out, he enlisted, in 1862, in the 114th New York Volunteers and took part in a number of battles, receiving a severe wound at Winchester in September, 1864. The bullet he received at this time he carried throughout his life and the effects of it may have contributed to some extent to the causes leading up to his death. He left the army in 1865, and went back to his studies, first at Oxford Academy and Institute, in Chenango County, then, from 1867 to 1871, at Yale College. On leaving the latter institution he was compelled to take up newspaper and other editorial work in order to acquire the necessary funds for continuing his education. He then spent two years at the Sheffield Scientific School of Yale University, graduating in 1874 with the degree of Ph.D. The greater part of his time during this stay at Yale University was devoted to the study of chemistry.

On leaving Yale University he acted for one year as the assistant to the professor of physics at the University of Pennsylvania, Philadelphia. He then took up the position of professor of sciences at the Riverview Military Academy, Poughkeepsie, a position which he held for a few weeks only, for, in the autumn of 1875, he received an invitation from the Pennsylvania Railroad to act as their chemist. He accepted the offer, and held this position up to the time of his death.

At the last meeting of the International Association for Testing Materials at Copenhagen, in returning thanks for his nomination as president of the association, Dr. Dudley stated that he had spent his whole life in testing, his thoughts no doubt carrying him back to the day, just 34 years previously, when he commenced the installation of his laboratory at Altoona, in which he was to carry out such useful work, not only for his company, but also for a large number of other concerns and institutions.

His work for the greater part was pioneer work; it covered in the course of a very short time the whole of the large number of materials of different kinds used in the building and the working of a railway, including both the track and the rolling stock; it led to the drawing up of complete series of standard specifications for all the classes of goods required. From the beginning he started minute investigations in the matter of quality and life of steel rails; he carried out these investigations systematically by testing for their physical and their chemical properties rails which had been in service for varying periods of time. His researches in this field, and the conclusions he arrived at, led to his introducing numerous variations in the steel-rail specifications which so far had been accepted.

Dr. Dudley was a pioneer in the investigation of the value of alloys for frictional bearings. He also made an exhaustive study of the most efficient size of bearings for railroad cars, and his experiments led to the adoption by his railroad of wide journals for the heavy cars. Dr. Dudley was elected a member of the Iron and Steel Institute in 1886, and he frequently took part in its discussions. His contributions to the proceedings of scientific associations and to the technical press, quite apart from his specifications for the Pennsylvania Railroad Company, are very numerous, and may be said to cover the whole field of railway construction and working, from the laying of the track to the adequate ventilation of passenger carriages.

Dr. Dudley was at one time president of the American Chemical Society, president of the American Society for Testing Materials and at various times he has occupied a prominent position in other organizations. He was also a member of numerous foreign technical institutions, and, as already stated, he had been four months ago elected president of the International Association for Testing Materials, a position in which by his wide experience and the universal respect in which he was held, he would have greatly forwarded the cause of the association—the unification of methods of testing. Dr Dudley's contributions in the application of chemistry to the industries will not soon be set aside nor quickly forgotten.

American Institute of Mining Engineers.

The following new members have accepted election to the American Institute of Mining Engineers:

Messrs. Donald [illegible] Rossland, B. C., Canada; [illegible] Marshall Cairns, Glasgow, Scotland; Samuel W. Cohen, Cobalt, Ontario, Canada; Raoul Gray Dufourcq, Arizpe, Sonora, Mexico; James Haskell Hoge, Salt Lake City, Utah; Frederick Charles Holmes, Santiago de Cuba, Cuba; Clarence T. Hopkins, Jerome, Ariz.; Archabald Stewart Hummel, High Bridge, N. J.; Percy Kenyon, Concepcion del Oro, Zacatecas, Mexico; Warren Lawson Klutty, Thomas, Ala.; S. Arthur Krom, Plainfield, N. J.; Henry M. Lancaster, Wallace, Idaho; Charles N. Lindley, New York City; Robert Livingstone Livingstone, Alberta, Canada; Eugene McAuliffe, Chicago, Ill.; James P. M'Carthy, Wallace, Idaho; Atpell Francis McEwen, Cobalt, Ontario, Canada; Henry A. Morris, Gowganda, Ontario, Canada; Duncan M. Munter, Huntingdonville, Jalisco, Mexico; James Negus, Bowen Mountain, New South Wales, Australia; John O. Nichols, Berkeley, Cal.; Horace L. Parsons, Garfield, Utah; John G. Petry, Denver, Colo.; Guy Hall Ruggles, Santa Rita, N. M.; Chard Olive Sanford, Globe, Ariz.; Charles H. Schlacks, San Francisco, Cal.; Gustave Schrader, Silver Creek, Cal.; Tock Kai Tse, Wickenburg, Ariz.; Rush J. Wire, Wallace, Idaho; James F. Callbreath, Jr., of Denver, Colo., was elected an associate member of the Institute.

Electrical Drive for Rolling Mills.

By Dr. A. S. McAllister.

In considering the driving of rolling mills by means of electric motors one should not lose sight of the fact that the motors are merely elements in a system the whole duty of which is to transmit energy economically from the point where it can be produced most conveniently to the places where it must be utilized to obtain the desired result. To only a very minor extent can electric motors, when substituted for other means for driving rolling mills, affect the sum total of energy actually utilized in the rolling processes or the rate at which this energy is employed. However, the electrical system, of which the motors form one part, when properly arranged for the purpose does affect in a pronounced manner the instantaneous rate at which the energy is produced, and to a limited extent the total amount of energy which must be produced. That is to say, the electrical system can conveniently make use of means for storing energy between the time when it is produced and when utilized, and it is highly efficient in the performance of its duty with reference to the transmission of energy.

The simplest method of adapting electric motors to rolling-mill service is to substitute for each steam engine previously used for the purpose a motor of equivalent maximum horsepower and install a generating equipment suitable for supplying energy to the motors. An electrical installation of this kind would possess certain advantages over the steam-engine equipment, such as efficiency in transmission, cleanliness in operation, and flexibility in control, but viewed from the electrical standpoint it is unnecessarily expensive. Each motor must be capable of exerting the maximum torque demanded of the shaft which it drives, which torque is reached for only a very small part of the cycle of operation, and hence it must be designed for a load which it will be called upon to carry only intermittently for very short periods. The significance of this statement is that each motor must be built of a size many times (from four to eight times) as large as the size of motor that would be required for carrying its average load. Moreover, the generating equipment must be designed for a large maximum load, while it will operate for a major portion of the time at only a fraction of the rated output, and hence will be excessive in first cost and not too highly efficient in operation.

A simple method for decreasing the cost of the generating equipment is to install a storage battery with regulating devices for causing the generators to charge the battery when the load on the system is light, and for allowing the battery to discharge into the system when the load is heavy. By the use of such a battery installation the generators can be designed for the average load on the system, and they will operate continuously at a high efficiency by carrying a load which fluctuates only slightly.

Direct-Current Motors.

When the older steam-engine practice is followed the rolling-mill motors must be of the reversing type and must be capable of accelerating quickly from rest to full speed. This requirement dictates the use of motors of the direct-current type, which are much superior to alternating-current motors for variable-speed and reverse-motion services. Although direct-current motors without special means for suppressing sparking have given excellent results in rolling-mill service, yet there can be no doubt that the severe duty imposed by the fluctuating torque of the rollers can best be performed by direct-current motors when they are provided with interspaced commutating poles. In fact, reversing rolling-mill service furnishes ideal conditions for the application of interpole direct-current motors.

Although the use of a flywheel directly with a reversible motor would be even detrimental to its performance, yet by supplying energy to the reversible motor through a flywheel-motor-generator set considerable advantages are obtained. The motor of the set is so designed that its speed decreases with increase of load; it could be of either the direct-current shunt-wound type or alternating-current induction type. The generator of the set is a direct-current machine, the voltage of which may be varied at will according to the demands of the reversible rolling-mill motor. The flywheel performs a useful service in storing energy from the supply system when the rolling-mill motor is idle and giving off energy to the generator of the set when the demand is greatest. Thus it permits the motor of the set to operate at a load which varies only slightly, although the load on the generator fluctuates enormously. By making the generator of the set a variable-voltage machine much of the energy which would otherwise be wasted in rheostats is saved and hence the efficiency is improved, but the size of the generator is not appreciably decreased thereby. For the purpose of preventing sparking when operating at low voltage with weakened fields and full value of armature current, the generator could be provided with interspaced commutating poles. The use of such interpoles permits the active material of either a generator or a motor to be proportioned for the mean effective load on the the machine rather than for the maximum load, as in the case when interpoles are not used.

An example of a flywheel-motor-generator installation is the equipment of the Illinois Steel Company, where use is made of a 1300-hp motor-generator set connected to a 100-ton flywheel for supplying energy to two 2000-hp reversing rolling-mill motors.

Alternating-Current Synchronous Motors.

In comparison with other motors which may be used for driving rolling mills the direct-current machine possesses the advantage of flexibility in speed control and the ability to receive energy directly from a storage battery. It is disadvantageous in possessing a commutator which requires much attention, and is limited in voltage to a value much below the e.m.f. at which energy can be transmitted economically over any considerable distance. So far as concerns transmission the synchronous alternating-current motor might be arranged to give satisfactory service, but its absolute constancy in speed ratio with the generator eliminates it from consideration where flywheels are to be used for energy storage.

Polyphase Induction Motors.

For the direct driving of non-reversing rolling mills no motor is better adapted than the polyphase induction machine. This motor has no commutator and hence cannot spark. Its torque speed characteristic is identical with that of the direct-current shunt-wound motor, for which it can be directly substituted. In comparison with this motor it is advantageous in being free from commutator troubles and not restricted to low voltages, and disadvantageous in that it cannot receive energy from a storage battery, and in its simplest form is limited to operation at practically a single speed. The disadvantages are of relatively minor importance and have been minimized by the methods outlined below.

When built with a constant secondary resistance—that is, with a squirrel-cage rotor—the polyphase induction motor operates in all respects like a shunt-wound direct-current motor with a constant resistance in its armature circuit. The machine tends at all times to accelerate to a certain definite speed, and under load runs below this speed by an amount depending directly upon the torque which it must exert. Like the shunt-wound motor it can exert its full-load torque at any speed below the normal full-load value, provided the resistance of the rotor circuit is correspondingly increased. Moreover, a combination of two induction motors in series arrangement can be used for obtaining lower speeds just as the armatures of the direct-current motors can be joined in series for half-speed operation. When thus employed the motors are said to be connected in concatenation. An example of the concatenated method of speed control of two induction motors is found at the rolling mill of the Edgar Thomson Steel Company.

So far as the operation of the motor itself is concerned best results are obtained when a polyphase induction machine is

arranged for operation at a practically constant speed without variation in its secondary resistance. Under these conditions the motor could be built with a squirrel-cage rotor, which may well be considered immune from all circuit troubles. Such a motor provided with a flywheel of such a size as to store and give off sufficient energy during each rolling cycle forms an ideally simple machine for the direct driving of a non-reversing rolling mill. Within all operating limits, the lower the resistance of the squirrel cage secondary the smaller may be the flywheel and the more efficient the operation of the motor, but the greater the fluctuations in the load on the supply system. The least load fluctuations are obtained with the heaviest flywheel and with a high value of secondary resistance—not, however, the highest possible value.

In any event the power demanded by the motor from the supply system must fluctuate, because the motor must vary its speed as it accelerates the flywheel in storing energy or allows the flywheel to decrease its speed in giving off energy to the rolls. The mean speed is such that the motor takes from the supply system that average value of power which, multiplied by the time of each cycle, represents the cyclic rolling energy plus the various losses; the fluctuation in speed is such that the flywheel delivers to the rolls the energy to represent all instantaneous excess of demand for power above the value given by the motor and absorbs energy when the motor power is greater than that being used by the rolls.

A flywheel designed to deliver to the rolls the total of the energy represented by all power above the mean value, while decreasing its speed from the mean value to the minimum permissible value, would more than fill the requirements by reason of the inevitable fluctuations in the power of the motor. By sacrificing some of the simplicity of the squirrel-cage rotor, it is possible to reduce materially the fluctuations in the power taken by the induction motor from the supply system. For this purpose the motor is provided with a coil-wound rotor equipped with slip rings so that the resistance in the secondary circuit may be varied as desired. The power taken by the motor could be kept absolutely constant by increasing the secondary resistance in direct proportion to the "slip" of the rotor from its no-load (synchronous) speed, the fluctuations noted above could even be reversed by subjecting the secondary resistance to variation greater than here assumed. The writer is not aware that the constant load scheme has ever been employed in rolling mills. However, the variable-resistance scheme is used at the Gary, Ind., plant of the Illinois Steel Company, where a storage battery serves to minimize the fluctuations in the load on the generators.

Electrochemical Energy Storage.

Mention has already been made of the fact that in comparison with the alternating current motor, the direct-current motor possesses an advantage in being capable of utilizing energy directly from a storage battery. At the Gary plant any disadvantage under which the induction motor would labor in this respect has been compensated for by the installation of special rotary converters as connecting links between the alternating-current supply leads and the storage battery. By means of these converters, which are of the split-pole variable-ratio type, the load on the alternating current generators is kept as nearly constant as desired in spite of the violent fluctuations in the load on the alternating current system. One of the most interesting features of the storage battery installations is a variable-voltage generator used for changing the excitation of the converters in accordance with the fluctuation in the load on the alternating-current system. This exciter can be adjusted to maintain the load on the generators at any desired mean value with the fluctuation minimized to any desired degree.

Relative Advantages of Electrochemical and Mechanical Energy Storage.

It will be observed that between the rolls at which the energy is utilized and the generators where it is produced, use is made of two devices for permitting the energy to be generated at a constant rate although utilized with extreme fluctuations in rate, namely, the flywheel and the storage battery. Although performing similar services, and thus assisting each other in producing the desired result, the flywheel and the storage battery possess distinctive characteristics with reference to the transfer of energy which preclude the one being substituted for the other or used exclusively.

The chief advantage of the flywheel resides in its ability to deliver its stored energy at practically any rate demanded. For example, a 50-hp motor-flywheel set could readily deliver energy at the instantaneous rate of 50,000 hp for a limited period, while a storage battery capable of supplying energy at this rate would have to be designed for about 12,500 kw hours; however the battery could deliver this same amount of power for a number of minutes. The significance of this statement is that energy stored in a flywheel is available for instantaneous use, while considerable time is required for extracting energy from a storage battery.

Where a limited amount of energy is to be used for a short time at a very high rate the flywheel is much less expensive and more satisfactory than the storage battery, but where a considerable amount of energy is to be stored for use at a relatively low rate (represented by cyclic intervals of several seconds) the battery is far preferable to the flywheel.

It is to be noted in this connection that the storage battery assists only the generating equipment while the flywheel is of assistance to the whole electrical installation; by its use the motors, transmission circuits, generators, and prime movers may be built for the average rather than the maximum load and operated at the best efficiency. In electrically driven rolling mills the flywheel may well be considered a necessary device. For the best service it should be used on the motor driving the rolls rather than on a generator set supplying energy to the rolling mill motor.

New Uses of Liquid Air and Oxygen.

Some interesting industrial applications of liquid air and of oxygen made from liquid air were noticed in a recent paper read by Mr. George Claude on November 10, 1909, before the Society of Civil Engineers of France.

Commercial plants for the production of liquid air by the Claude process or by the Linde process exist in various European countries (there is also quite a large one in this country using the Linde process, in Buffalo, N. Y.) Their chief product is compressed oxygen, and the principal applications of the oxygen are autogenous welding with the oxy-acetylene flame, cutting of metals with the oxy-oxy-acetylene flame, and the manufacture of artificial precious stones.

But the price of oxygen thus produced is still comparatively high, as Mr. Claude points out, on account of the large expense for compressing and bottling the oxygen gas in cylinders and the shipping expenses. The cost of the oxygen gas would be greatly reduced if it was required in large quantities on the spot. An essential item in the cost is represented by the pressure to which the air under treatment must be compressed. This pressure is given by Claude as 18 atmospheres for apparatus producing 100 cu m (3530 cu ft) of oxygen per hour and is estimated as 10 atmospheres for 1000 cu m (35,300 cu ft).

At present 1 cu m (35.3 cu ft) of oxygen is obtained per hp-hour in apparatus producing 50 cu m (1765 cu ft) per hour. The figure of 1.25 cu m (44 cu ft.) of oxygen per hp-hour is guaranteed by the Société de l'Air Liquide for apparatus producing 200 cu m (7060 cu ft) per hour, and the figure of 1.75 cu m (62 cu ft) of oxygen per hp-hour represents the hopes of the manufacturers for apparatus producing 1000 cu m (35,300 cu ft) per hour.

A plant for the yearly production of 9,000,000 cu m (1,765,000,000 cu ft.) of pure oxygen requires not more than 20 m by 30 m (65 ft by 98 ft) floor space and 15 attendants.

For a plant, to be erected with apparatus producing 200 cu. m (7060 cu. ft.) of oxygen per hour, Mr. Claude's company has guaranteed that the cost of producing 1 cu. m (35.3 cu. ft.) of oxygen, including amortization, will be slightly more than 0.6 cent; that is, figured on the basis of the cost of 0.4 cent per hp-hour (an exceedingly low price which is thought to be justified because blast-furnace gases are used in driving the gas engines for power production at that place).

A very important and interesting experiment on a large scale is soon to be made by a Belgian iron and steel plant, the Société d'Ougrée Marihaye, with respect to the enrichment of the air with oxygen for the blast in one of their blast furnaces and converters. (We comment on this development in our editorial pages.)

At the conclusion of his lecture Mr. Claude showed a number of experiments, like the liquefaction of oxygen in contact with liquid nitrogen; the condensation of atmospheric air on the outside of an iron bottle containing liquid nitrogen; further the fact that coke maintained at the temperature of liquid air absorbs gases with such energy that it is possible to realize rapidly a vacuum of less than one-ten-thousandth of a millimeter. Mr. Claude also subjected a current of illuminating gas fed to a burner, to the action of liquid air; the result was a modification of the flame which assumed the characteristic appearance of the hydrogen flame. This experiment indicates the possibility of a cheap process for making hydrogen by partial liquefaction of water-gas. Other experiments illustrated the ease of recovery of volatile substances in chemical industries by refrigeration, such as ether and alcohol in the manufacture of artificial silk, and the facility of extracting neon and helium from the atmosphere.

* * *

In this connection it is interesting to report a lecture delivered November 18, 1909, before the Polytechnic Association of Berlin, by Dr. H. ERDMANN on the technical application of liquid oxygen. (*Chemiker Zeitung.*)

Dr. Erdmann first discussed briefly the chemical properties of the liquid gas and also described a modified arrangement for investigation of its purity by means of the aerometer. It is possible to utilize liquid oxygen at the same time for three purposes, namely, to utilize its cooling effect, the pressure, and its chemical energy.

The consumption of liquid oxygen is much greater than is generally supposed, although we have no accurate statistics regarding it. Three methods of manufacture are in use. By the Brin method barium oxide (BaO) is heated in a current of atmospheric air to form barium peroxide (BaO_2). The air current is then stopped, and the barium peroxide reheated in a partial vacuum, whereby oxygen is given off. By the second, the electrolytic method, the gas is obtained from water, but this is economical only when there is use at the same time for the hydrogen generated simultaneously with the oxygen in equivalent proportion. Electrolytic cells for this purpose have been devised by Schuckert, Garuti, Schmidt and others. The third method, based on the fractional distillation of liquid air, is now very largely employed in Europe. For operation on a large scale the cascade principle, which was first used by Pictet in 1877, is used to advantage. The lecturer mentioned briefly the processes of Cailletet, Kamerlingh-Onnes, Claude, Hildebrand, and Linde.

Altogether there is annually produced in Germany 8000 cu. m. (282,500 cu. ft.) of oxygen (meaning evidently oxygen gas at atmospheric pressure) by the Brin method, 342,000 cu. m. (12,000,000 cu. ft.) by the electrolytic method, and 2,200,000 cu. m (77,700,000 cu. ft.) by the fractional distillation of liquid air. The average cost for 1 kg of fluid oxygen amounts to about 10 pfennigs.

The oldest use found for oxygen is in explosives, oxygen cartridges not being dangerous. In recent years oxygen has found use in the production of light. In this connection was mentioned the Nürnberg light, which it has been found consumes very little illuminating gas and produces less heat than the ordinary gas lamp. It is also more hygienic since the oxygen is supplied to the flame and is not, therefore, taken from the air, thus contaminating the latter. In metallurgy oxygen finds many uses; for instance, in the oxy-hydrogen and oxy-acetylene flame for autogenous welding and cutting of metals. Oxygen is also used in the production of fused quartz (silica) vessels. Oxygen used in medicine must have the highest purity, this accounts for the higher price. According to Michaelis, oxygen, which is 96-97 per cent pure, costs 6 marks ($1.50) per cubic meter, while 99 per cent oxygen costs 10 marks ($2.50).

Platinum Thermometry at High Temperatures.

The Bureau of Standards has already produced quite a number of excellent researches on pyrometry, which are not only of a high scientific standard, but of great practical importance. Recently a long investigation carried out by Dr. C. W. WAIDNER and Dr. G. K. BURGESS, at the Bureau of Standards, on platinum resistance thermometers at high temperatures has been concluded. The general conclusions are as follows:

First with respect to temperature scales. Temperatures defined by the resistance thermometer of pure platinum calibrated by Callendar's formulæ at 0°, 100° and 444.7° (the boiling point of sulphur), agree with the temperatures on the generally accepted gas scale in the range 0° C. to 1100° C. to within the degree of reproducibility of the latter.

Thermometers made of impure platinum, and calibrated in the same way, do not define the same temperature scale as that of pure platinum, the divergence increasing with the impurity of the metal.

If thermometers of impure platinum are calibrated at a fourth temperature, such as the silver freezing point, and the difference coefficient of the Callendar formula is written $\delta = a + bt$, then the scale so defined by these thermometers is brought into very close agreement with that of the thermometers of pure platinum.

The Dickson formula $(R + a)^2 = p(t + b)$ is not applicable to either platinum or palladium thermometers at high temperatures.

The palladium thermometer, calibrated by the Callendar method, gives temperatures agreeing to 1° with the scale of the platinum thermometer up to 600°. It requires a fourth degree equation to express its resistance-temperature relation from 0° to 1100°.

The following table of freezing points represents the scale of the resistance thermometer of pure platinum as determined from the investigation, using only the purest metals:

	Metal									
	Sn.	Cd.	Pb.	Zn.	Sb.	Al.	Ag_2Cu_2.	Ag.	Cu.	$Cu\text{-}Cu_2O$.
Freezing point	231.92°	321.01	327.43	419.37	630.71	658.0	779.20	960.9	1083.0	1063.2
Average deviation for purest metal	.02	.02	.10	.02	.30	.5	.25	.20	.5	.3
Reproducibility factor	.06	.26	.10	.06	2.3	1.2	...	...	1.0	...

The average deviation of a single observation is a measure of the precision attained when two or more thermometers were used in a single metal sample. The reproducibility factor is the average deviation of the metals, designated as c.p., or better, from their mean F.P.

Thermocouples of Pt, 90Pt — 10Rh and Pt, 90Pt — 10Ir, calibrated at three temperatures in terms of the formula $E = a + bt + ct^2$, define a temperature scale in the interval 200° to 1100°, which is in agreement with the platinum-resistance scale at intermediate temperatures to within 0.3°.

As to the behavior of platinum thermometers the authors

conclude that when used at high temperatures the constants of platinum thermometers undergo gradual changes, which necessitate frequent recalibration in work of high precision. The use of thermocouples for work above the F. P. of silver is, therefore, much less laborious.

These changes in thermometric constants are greatly reduced, but not completely eliminated, by annealing the thermometers for at least several hours at a temperature higher than that at which they are subsequently to be used.

For thermometers of pure platinum, the changes in their constants after the thermometers have been annealed, are very much less than for those of impure platinum.

These changes are least for pure platinum wires of large diameter and suspended free from strains.

For impure platinum wire the effect of high temperatures is such as if the wire became purer, possibly because of the evaporation of impurities, for example, iridium. If the platinum is pure, the slight changes indicate a contamination of the wire and the effect of strains. The total change observed is a resultant of the effects of strains of annealing and of contamination and purification.

Calibration Temperatures.

As to calibration temperatures the authors state that the freezing points of the pure metals are the most satisfactory calibration temperatures, being superior to boiling points in constancy, ease of manipulation, and reproducibility. Unless a very slow rate of heating is used, melting points are less satisfactorily fixed and apparently slightly higher than freezing points.

The temperature of the separation of the silver-copper eutectic is an entirely satisfactory fixed point at 779.2°, when the alloy is of the eutectic composition, or about 72 Ag — 28 Cu. The eutectic point of copper-cuprous oxide is also a satisfactory calibration temperature at 1063.2°, when proper experimental precautions are taken to maintain the eutectic composition.

Boiling Point of Sulphur.

The authors also made an extended investigation of the boiling point of sulphur. They find the temperature defined by the vapor of sulphur boiling at known pressure and under carefully specified conditions is a most satisfactory fixed point, reproducible to a few hundredths of a degree. These conditions are, briefly:

(a) Sulphur to be boiled in a glass tube 4 cm to 5 cm diameter and of sufficient length to insure ample depth of immersion in the vapor (tube about 40 cm satisfactory).

(b) Sufficient depth of liquid sulphur to avoid superheating.

A criterion for the above conditions is absence of change in the observed resistance when the thermometer with its attached radiation shields is moved some cm up and down the tube.

(c) Surrounding coil of thermometer with a suitable radiation shield to avoid the cooling effects of the condensed sulphur running down the stem of the thermometer and of radiation to the cooler parts of the apparatus.

Both gas and electrically heated S.B.P. tubes were used; the former gave a temperature 0.03° or 0.04° higher than the latter.

The determination of the S.B.P. by different observers is discussed at length. The determinations of these observers are in satisfactory agreement, the values found ranging, with one exception, from 444.5° to 444.7°. The bearing of some recent work, with the gas thermometer on the value of the S.B.P. is considered, which shows that the above value may be too high. The tendency, however, is not sufficient as yet to warrant any change in the generally accepted and widely used value of the S.B.P.

For details of this interesting investigation the reader is referred to the very long and full report of Messrs. Waidner and Burgess in No. 2 of Vol. VI (1909) of the *Bulletin* of the Bureau of Standards.

Natural Gas Production.

According to a chapter of "Mineral Resources, 1908," by Mr. B. Hill, just issued by the Geological Survey, the approximate value of the natural gas produced from wells and consumed in the United States in 1908 was $54,640,374, being greater than that of any previous year. There was a slight decline in 1908 in the Eastern States, as compared with 1907, but this loss was more than made up by substantial gains in the States of the Middle West and South. A further examination of the tables for the last three years shows at least three interesting tendencies: An increasing quantity of gas used for domestic purposes, a decreasing quantity consumed for industrial purposes, and an increased price for the gas.

The production of crude petroleum in 1908 is valued at $120,106,749. Taken with the natural gas this made a combined annual valuation of $174,329,148 for the two products. An examination of the table of production covering the period from 1882 to 1908 shows that the output of natural gas rose rapidly from a value of $215,000 in 1892 to $22,620,873 in 1888, fell gradually in the next eight years to $13,002,512 in 1896, a little more than doubled in five years to $27,066,077 in 1901, a little more than doubled again in the next six years to $54,222,309 in 1907, and, in spite of the financial difficulties beginning in 1907, increased slightly in 1908. This remarkable record seems to indicate that the producton of natural gas has become one of the great established industries of the country, an indication borne out by the extension of the gas districts in the Appalachian field, by the development of the mid-Continental and Gulf fields, which has practically only begun, and by the systematic efforts being made to conserve the consumption of this most useful, convenient and luxurious fuel.

The total number of natural-gas wells productive December 31, 1908, was 21,375. During the year there were 1241 wells abandoned and 2894 drilled. This latter number of wells is itemized as 2148 gas and 746 dry.

During 1908 natural gas to the value of $22,003 was imported for consumption. No exports were recorded. The report shows that Pennsylvania not only leads all States in the value of its gas production in 1908, but also in the combined value of its natural gas and petroleum production. The statistics of the natural gas industry, as given in the table of distribution, show that the value of the gas consumed in this State in 1908 was $20,678,161, as compared with $22,917,547 in 1907, a decrease of $2,239,386. This decrease was due to a falling off in consumption, the quantity decreasing from 164,541,170,000 cu. ft. in 1907 to 147,790,097,000 cu. ft. in 1908. The average price per 1000 cu. ft. was 13.99 cents in 1908, as against 13.9 cents in 1907, a slight advance. The greatest decline was in gas utilized for industrial purposes, the quantity and value decreasing from 119,700,431,000 cu. ft., valued at $12,070,625, in 1907, to 105,587,229,000 cu. ft. valued at $10,536,644, in 1908, this decline being partly due to the lessened demand for gas as a result of the general depression in business which so largely affected the manufacturing districts of this State in 1908. In some instances wells owned by manufacturing establishments which were idle were closed all the year. In the domestic consumption of gas in 1908 there was a decline of 2,037,886,000 cu. ft. in quantity and of $705,405 in value as compared with 1907.

The preliminary report of the Canadian Department of Mines places the value of Canada's natural gas production at $1,012,060. In 1907 it was worth $815,032.

Iron and Steel Institute.—The annual general meeting of the British Iron and Steel Institute will be held at the Institution of Civil Engineers, Great George Street, London, S. W., England on Wednesday and Thursday, May 4 and 5, 1910. The annual dinner will be held, under the presidency of the Duke of Devonshire, in the Grand Hall of the Hotel Cecil on Wednesday, May 4. The autumn meeting will be held at Buxton on Sept. 27, 28 and 29, 1910.

The Magnetic and Electrical Properties of the Iron Copper Alloys.

BY CHARLES F. BURGESS AND JAMES ASTON.

In connection with an extended investigation of iron alloys, carried out at the Chemical Engineering Laboratories of the University of Wisconsin, under a grant of the Carnegie Institution of Washington, a series of tests were made upon the iron-copper group. The results of various physical tests, including hardness, forgeability, and tensile strength, were described at the October, 1909, meeting of the American Electrochemical Society,[1] and were reprinted in the *Electrochemical and Metallurgical Industry* of December, 1909.

This paper has to deal with the magnetic and electrical properties of the same iron-copper series and is, therefore, supplementary to the one mentioned above.

The details of the preparation of the alloys and of the test samples were given in the previous article, and need not be dwelt upon to any extent here. Electrolytic iron formed the basis of the alloys, together with alloying materials of a corresponding degree of purity; therefore, any properties noted in the tests may be considered as due to the effect of the added elements alone.

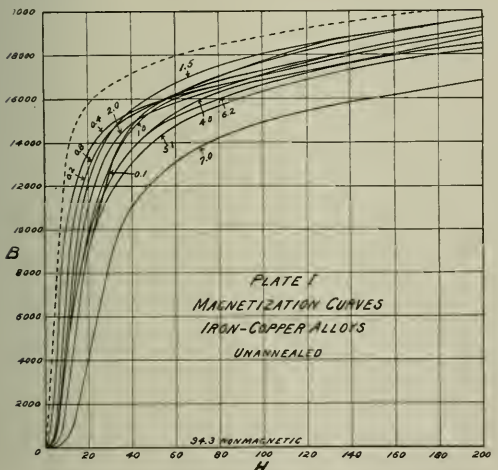

FIG. 1.—MAGNETIZATION CURVES, UNANNEALED.

Tests were made upon 24 binary alloys of iron and copper, and upon 21 alloys with copper-silicon, copper-aluminium, copper-tin and copper-arsenic.

Of the binary alloys the following have been analyzed, and form the basis of the discussion of this series.

	Per Cent Copper.	
Bar.	Added.	Analysis.
147B	0.1	0.089
158A	0.2	0.202
158B	0.4	0.422
158D	0.8	0.804
147H	1.0	1.006
147J	1.5	1.510
158G	2.0	2.005
158I	4.0	3.990
158J	5.0	5.070
158K	6.0	6.160
147U	7.0	7.050
86F	95.0	94.340

The metals mixed in precisely the added proportions. Ingots with all percentages of copper between 7 and 95 per cent were made, but it was impossible to forge this intermediate series until the copper content reached 90 per cent.

[1]Physical Properties of Iron-Copper Alloys, by C. F. Burgess and James Aston. Trans. Am. Elec. Soc. Vol. XVI, 1909.

Magnetic Tests.

The magnetic tests were made upon an Esterline permeameter under four different heat treatments—first, as forged; second, after heating to 675° C. and slowly cooling; third, after heating to 1000° C. and slowly cooling; fourth, after heating to 900° C. and quenching in water. The results are noted in Tables I and II and in Plates I, II, III and IV. All tests are compared to standard bar of electrolytic iron of high quality; the curve for this bar is indicated in the plates by a dotted line. In the unannealed condition the materials fall into two groups,

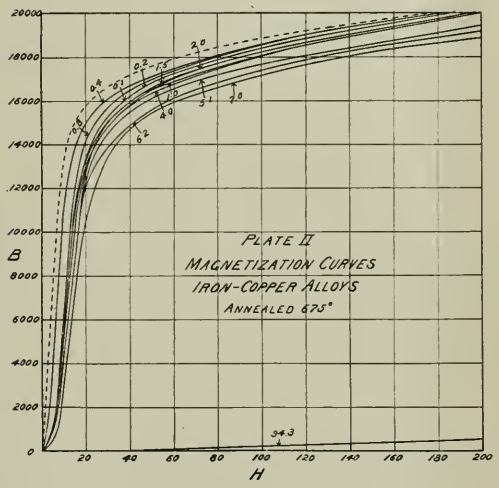

FIG. 2.—MAGNETIZATION CURVES, ANNEALED 675°.

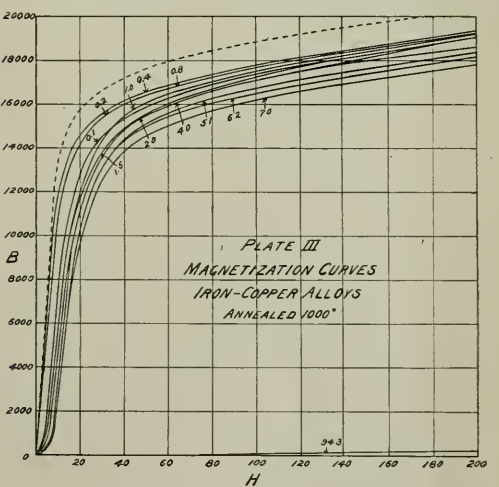

FIG. 3.—MAGNETIZATION CURVES, ANNEALED 1000°.

with those of 1.5 per cent and less irregularly mixed and of the higher magnetic quality; above 2 per cent the permeability falls off rather quickly as the copper content is increased. This is in line with the hardness tests noted in the previous paper. None of the entire series, however, is of a quality worthy of mention; on the other hand, only bars of 4 per cent and up-

warps if copper be conspicuously poor. Bar 86F, with 94.34 per cent of copper, is non-magnetic.

Annealing at 675° has greatly improved the quality of all of the bars, and the curves now fall with considerable regularity in positions indicating a decrease of permeability with increase of copper content. The two best materials are bars 158B with 0.422 per cent Cu, and 158D, with 0.804 per cent copper, the former is but little inferior to the standard electrolytic curve.

Annealing at 1000° has not changed the relative positions of the curves, but has had the effect very generally observed in all of our work of decreasing the densities reached in the upper ranges. For the lower values of H (below 10) there has been an increase of permeability for those alloys of a copper content of less than 1 per cent, but for a percentage of one and upwards there is a deterioration for all values of H.

Quenching at 900° shows practically no change in quality from that of the previous treatment, the annealing at 1000°.

In all conditions subsequent to the unannealed state it has been possible to induce a small magnetic flux in bar 86F, with 94.34 per cent Cu; but the amount is too slight to warrant one in classing this material as other than non-magnetic.

No specific deductions can be drawn from the retentivity which were not analyzed give figures somewhat at variance with the results discussed above, in that three of the bars were of very high magnetic permeability

Table II.—Coercive Force and Retentivity.

Bar	Per Cent Copper	Coercive Force H (Max.) = 200 Unann.	Ann. 675°	Ann. 1000°	Quench 900°	Retentivity H (Max.) = 200 Unann.	Ann. 675°	Ann. 1000°	Quench 900°
117A	....	5.5	6.2	3.1	2.5	12,300	13,800	10,000	8,000
147B	0.09	13.0	8.7	12.1	4.3	12,700	12,000	10,100	8,400
158A	0.20	7.0	9.3	4.0	3.5	11,100	13,300	8,400	8,400
158B	0.42	7.0	6.0	3.7	3.6	9,900	13,300	8,600	9,300

147U	7.05	400	3,000	2,400	2,950	4,200	10,400	10,150	8,400	12,150	15,450	14,950	14,200	14,900	17,200	16,500	16,150
86F	94.34	0	0	0	0	0	0	0	0	0	200	100	100	0	50	0	0

values of Table II. The values of coercive force follow a general tendency to diminish with the successive treatments, although in a few minutes the reverse is conspicuously evident. The values are at no time low, except for those alloys

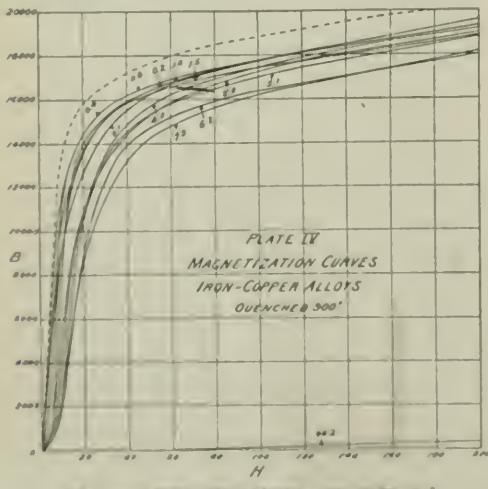

Fig. 4.—Magnetization Curves Quenched 900°

of less than 1 per cent copper after heating to the higher temperatures.

The results of the latter tests on the 12 binary copper bars

In the light of previous deductions, and because of the absence of accurate analyses, no conclusions will be drawn regarding these high values. They may be the result of high purity of the electrolytic iron and the absence of the intended content of the alloying elements.

Summarizing, it may be said there is no advantage to be gained in adding copper to iron if a good magnetic permeability is wanted. The quality deteriorates almost in proportion to the added copper content. On the other hand, it may be said that there is nothing to be feared from the effect upon the magnetic quality of the small percentages of copper ordinarily found in commercial materials.

In our previous discussions of the physical properties of the iron-copper alloys, stress was laid upon the fact that the alloys

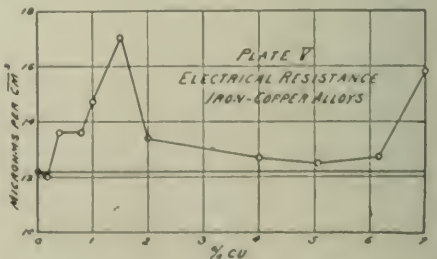

Fig. 5.—Electrical Resistance

with copper content of from 1 to 2 per cent were entirely comparable with the iron-nickel alloys with percentages of nickel from three to four, which is the range ordinarily adopted in

commercial practice. Direct comparison of the magnetic properties of the above-mentioned ranges is not possible, since we do not have the necessary data for the nickel series. However, it is worthy of mention that the magnetic data of the iron-copper alloys of the above-noted percentages is very similar to that for iron-nickel alloys of 1.93 and 7.05 per cent nickel, and they may, therefore, be taken as equal in magnetic quality to the nickel steels. Again, inspection of the magnetization curves, particularly after annealing at 675° C., shows permeabilities for the alloys of 1 to 2 per cent copper sufficiently high for commercial purposes, should their use be desired because of the increased tensile strength.

Electrical Conductivity.

Results of measurements of electrical resistance are given in the following table and in Plate V. The data are given in microhms per cubic centimeter; also in terms of the relative resistance compared to the same standard bar of electrolytic iron used in the magnetic tests. The bars had all been quenched at 900° C.:

ELECTRICAL RESISTANCE.

Bar.	Per Cent Cu.	Microhms Per Cu. CM.	Relative Resistance.
147B	0.09	12.2	1.01
158A	0.20	12.0	0.99
158B	0.42	13.6	1.12
158D	0.80	13.6	1.12
147H	1.01	14.7	1.22
147J	1.51	17.0	1.41
158G	2.01	13.4	1.11
158I	3.99	12.7	1.05
158J	5.07	12.5	1.03
158K	6.16	12.7	1.05
147U	7.05	15.8	1.31
86F	94.34	3.9	0.24

The conductivity is in no case above that of the standard iron bar, except for bar 86F, with 94.34 per cent Cu. Here the resistance is only one-fourth that of the iron; however, this alloy really belongs at the copper end of the series.

The resistance rises rapidly to a maximum of 17 microhms per cubic centimeter, at a copper content of 1.51 per cent. Between 2 and 6 per cent copper the conductivity is but little inferior to that of the iron, while at 7 per cent the resistance has again risen to 1.31 times that of the standard.

Later measurements upon numerous unanalyzed iron-copper alloys give results so irregularly scattered in relation to those here given that they should be accepted with caution.

CHEMICAL ENGINEERING LABORATORIES,
UNIVERSITY OF WISCONSIN.

The Failure of a Plant for Making Cyanide by the Fixation of Atmospheric Nitrogen.

Records of failures are as interesting and instructive as records of successes, but they remain usually unwritten. An example from the rule is an article by Mr. WILLIAM BETTEL in the *South African Mining Journal*, August 7, 1909, page 640, and reprinted in the *Journal* of the Chemical, Metallurgical and Mining Society of South Africa, November, 1909, page 187. Mr. Bettel writes as follows:

Spasmodic attempts at the manufacture of cyanide, based upon reactions, discovered over 60 years ago, for the fixation of atmospheric nitrogen as an alkaline—or alkaline earthy—cyanide have from time to time been made with more or less success, but I do not think that a description of a plant which was in use in the early nineties, but subsequently closed down owing to its unpayable nature, has hitherto appeared in print.

The works I refer to were in Scotland. A coal-gas works was obtained, suitable additions were made, the process being carried out as follows: Charcoal, selected for its low ash contents and even porosity, was soaked in a saturated solution of potassium carbonate. The charcoal was drained and dried, charged into gas retorts and dry nitrogen (from the air), deprived of oxygen as completely as possible, was passed over the heated charcoal ($+ K_2CO_3$) until the absorption of nitrogen slackened. The charges were then "drawn" out of contact with air, being cooled by the incoming dry nitrogen, and fresh charges introduced. On the average about 25 per cent of the potassium salt was converted into cyanide by the following reaction: $K_2CO_3 + 2\,C_2 + N_2 = 2\,KCN + 3\,CO$. At the same time a certain amount of metallic potassium was formed by the reduction of the carbonate with charcoal: $K_2CO_3 + C_2 + 3\,CO$. The carbon monoxide under certain undefined conditions formed a carbonyl (potassium carbonyl) $K_4(CO)_4$, which has explosive properties.

The crude cyanide so produced was subjected to systematic lixiviation and the saturated solution of $K_2CO_3 + KCN$ decomposed by the CO_2 present in gases from a slow-combustion furnace fed with gas-coke. The operation consisted in passing the gases containing nitrogen and carbon dioxide (with some impurities), through a tower containing coke over which the stream of cyanide solution trickled. The decomposition was as follows: $2\,KCN + 2\,H_2O + 2\,CO_2 = 2\,HCN + 2\,KHCO_3$.

The exhausted liquor, after suitable concentration, was reused for saturating the leached and dried charcoal, with suitable additions of fresh material. The saturated charcoal was then dried as before and went through the above-mentioned cycle of operations.

The hydrocyanic acid gas swept out of the "scrubber" by the nitrogen was absorbed by a cold-water spray in another tower, also filled with coke, the gas being dissolved in the water as hydrocyanic acid. This liquid was collected in stills (actually large steam boilers) and heated with steam coils. The HCN, with some water vapor, passed through a coil cooled to 25° C. to 28° C., which allowed the water to condense and return to the still, while the HCN passed forward. This gas was then condensed in another coil, kept as cold as possible, the liquefied HCN dropped into caustic soda, the compound NaCN, H_2O being formed. The crystals were "fished out" and "centriffed." The trace of caustic soda adhering to the cyanide became converted into sodium carbonate, and the crystals were sold as 80 per cent (equivalent of KCy) strength. By long-continued drying the combined water could be removed to a considerable extent, the "cyanide" content being similarly increased.

When the works were started it was expected that the total cost of manufacturing cyanide (based on 98/100 KCy) would be about 3 d. (6 cents) per pound, but the actual cost was about 1 s. (25 cents) per pound. Among the causes which contributed to this unexpected increase of cost were the following:

(1) Loss of carbonate of potassium by formation of silicate of potassium from ashes in wood and impurites in coke.

(2) Loss of carbonate of potassium by formation of sulphide, sulphate and sulphite of potassium from sulphur compounds in furnace gases and from coke.

(3) Waste of charcoal from oxidation due to porosity of retorts.

(4) Excessive fuel consumption (over that calculated as necessary) for power and heating.

(5) Excessive wear and tear through damages to plant from explosions, etc.

I have in my possession some of the sodium cyanide made by this method, but it has lost most of its water of crystallization. Modern methods in vogue in Europe and America for the manufacture of cyanide of sodium and the mixed (98/100 per cent) cyanides of potassium and sodium are now brought to such a state of perfection that it seems useless to try and make cyanide here by the fixation of atmospheric nitrogen. Recent experiments have convinced me that—in this country at least—such processes are foredoomed to failure from a financial standpoint.

Gold Refining.

The Wohlwill process of gold refining with the recovery of platinum has been the subject of quite a number of articles in this journal. (See especially the article by D. K. Tuttle, Vol. I, page 157, and the articles by the inventor himself, Dr. Emil Wohlwill, in our vol. II, pages 221 and 261, and vol. VI, page 450.) A recent patent of the Norddeutsche Affinerie A. G., with which Dr. Wohlwill is connected (German patent 207,555, Sept. 22, 1908), is exceedingly interesting since it refers to a simple modification which appears to broaden greatly the scope and applicability of the Wohlwill process.

If gold, rich in silver, is refined in a solution of gold chloride containing pure hydrochloric acid or other chlorides, it becomes necessary to remove mechanically from time to time the layer of silver chloride which forms on the anode; in practice it has been found that this is necessary whenever the silver content in the anode is more than 6 per cent. If the layer of silver chloride is not removed from the anode, chlorine is set free and this will take place at an earlier stage of the process, the higher the current density used and the higher the silver content of the anode.

It then becomes necessary to reduce the current density, but this increases considerably the expense due to the smaller output and the increased capital charges per unit weight of output.

A novel arrangement by which these difficulties are overcome is the use of a pulsating current instead of a constant direct current. This is best obtained by connecting a direct-current dynamo in series with an alternating-current dynamo. As long as the voltage of the latter is lower than that of the former, the current obtained by the superposition of the two currents will always have the same direction, but will change periodically from a minimum to a maximum. While such a current produces some good effect in electrolytic gold refining, it is preferable for practical purposes to use an alternator with a higher (maximum) voltage than the direct-current dynamo in series

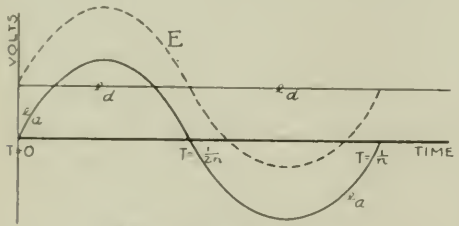

DIAGRAM OF PULSATING CURRENT.

with it. In this case we get a current which has not always the same direction, but is really an alternating current symmetrical with respect to the voltage curve of the direct current dynamo. The adjoining diagram illustrates the voltage curves. The straight line ca is the curve of the direct-current dynamo voltage, the curve c_a is the curve of the alternating current dynamo. The dotted curve E is the resulting voltage obtained by the superposition of the alternating current upon the direct current. It is symmetrical with respect to the straight line ca.

The electrolytic effect is, according to Faraday's law, equal to the effect of the direct current alone. In other words, the total gold deposited on the cathode can be found from Faraday's law, on the supposition that only the direct current is passing.

The effect of the alternator in series with the direct-current dynamo manifests itself in various ways. The voltage at the terminals of the refining cell measured with a direct-current voltmeter is less than if an absolutely constant current is used. Further, the anodic reaction is essentially influenced by the alternating current. It is possible to increase considerably the anodic current density without causing the development of chlorine gas and without scratching off the layer of silver chloride.

A limit is set to the increase of anodic current density in so far as a relatively weak development of oxygen gas sets in when by increasing the current density the voltage reaches that amount for which chlorine would be set free with a purely direct current. The evolution of oxygen is first so small that the resulting decrease of ampere-hour efficiency is comparatively unimportant. It has even a certain advantage, since it facilitates the dropping off of the silver chloride layer. With increasing current density the evolution of gas becomes stronger. The limit of the current density above which one should not go without decreasing unduly the ampere-hour efficiency, depends on the content of silver in the anodes and on the value of the alternating current strength.

The permissible limit of the direct-current density (amperes per square inch of anode) is the higher, the less the content of silver and the higher the ratio of alternating-current strength to direct-current strength. As soon as a strong gas development takes place at the anodes (more than a few small bubbles) it becomes necessary to decrease the direct current density while the alternating current is not changed, or to increase the alternating current while the direct current remains unchanged.

As an example it is mentioned that if raw gold containing about 10 per cent of silver is treated according to the original Wohlwill process, an anodic current density of not more than 750 amp per square meter must be used, and in this case it is necessary to scratch off the silver chloride from the anode every 45 minutes. When using an alternating current, the strength of which is about 1.1 times that of the direct current, it is possible to maintain an anodic direct-current density of 1,250 amp per square meter without any necessity of scraping off the silver chloride.

The method also enables one to treat by the electrolytic refining process alloys much richer in silver than is possible with direct current alone. For instance, gold containing 20 per cent of silver can be refined if the ratio of the alternating current to the direct current is 1.7 to 1 and it is possible to use in this case an anodic direct-current density of 1200 amp per square meter. With lower direct-current densities the process is applicable also for gold still richer in silver, and appears to cover now all cases which occur in practice.

The use of a pulsating current and the resulting possibility of employing high-current densities involves another important advantage. In the original Wohlwill process employing direct current alone, about 10 per cent of the gold of the anodes passes as a finely subdivided dust into the slime and must be recovered by chemical means. If, however, a pulsating current is used, gold passes into the slime only at the beginning of the process as long as the anode is not completely covered with silver chloride. Later on practically no gold whatever passes into the slime.

The slimes, therefore, consist essentially of silver chloride and its spongy structure causes it to drop off by itself. Since at the beginning of electrolysis some little gold always passes into the slime and mechanical losses from the anode cannot be entirely avoided, especially near the end of the refining process, the slime will always finally contain some gold, but generally not more than 1 per cent of the gold content of the anodes. The saving of interest due to this considerable reduction of the gold remaining in the slimes represents a very essential advantage.

On account of the small amount of gold lost from the anode into the slime it is preferable to use a pulsating current instead of a direct current, even in such cases in which gold poor in silver is to be refined.

Whenever an especially high current density of more than 1000 amp per square meter is not of importance, the process has the advantage that the amount of pure hydrochloric acid or of chlorides added to the cell may be much smaller than with

direct current alone. With gold which contains little silver, electrolysis with a current density of 1000 amp per square meter with a purely direct current requires the addition of about 3 per cent hydrochloric acid and the electrolyte must be heated to a temperature of 60° C. or 70° C. The superposition of alternating current upon the direct current permits the use of only one-fourth of the amount of hydrochloric acid (which gives a solution containing about 1 liter of hydrochloric acid, 1.19 s.g., for 60 liters solution—that is, about 7 or 8 grams of hydrochloric acid per liter). On the other hand, if a solution containing 3 per cent HCl or more is used and if the current density is not above 800 amp or 1000 amp per square meter, it is no longer necessary to raise the temperature of the electrolyte to 60° C. or 70° C.

When carrying out the process with a purely direct current the heating of the electrolyte is absolutely necessary, since otherwise the gold is precipitated in form of a dark brown or black powder. This is true even if a current density of less than 500 amp per square meter is used, which seems absolutely impractical in view of the increase of interest charges. So much about the effect on the anodic reaction.

The application of a pulsating current, however, permits also an increase of the cathodic current density in a hot solution; or if the cathodic current density is below 1000 amp per square meter it is possible to obtain perfectly dense coherent deposits even from a cold solution.

The process is carried out in practice as follows: A direct-current and an alternating-current dynamo are connected in series and the voltage of the direct-current dynamo is regulated so that a direct-current ammeter (which does not indicate alternating current) indicates the desired direct-current strength in amperes. If this direct-curent strength is id amp and if it is intended to use an alternating current with an effective* value of ia amp, the effective value of the pulsating current obtained by the superposition of the direct current upon the alternating current is $I = \sqrt{id^2 + ia^2}$. This is the total effective current I as measured by a hot-wire ammeter (the action of which depends on the Joulean heat).

A hot-wire ammeter is, therefore, used in series with the direct-current ammeter and the voltage of the alternating-current machine is now regulated until the hot-wire ammeter shows that the alternating current has reached the correct value. If, for instance, it is intended that the "effective" value of the alternating current should equal the direct current, both being equal to 200 amp, the hot-wire instrument must indicate $\sqrt{80{,}000} = 283$ amp.

The total voltage which determines the power consumption is also measured by a hot-wire instrument. Its value depends on the strength of the total current. If, for instance, raw gold is refined which contains about 10 per cent silver, it is recommended to use a direct-current density of about 1250 amp per square meter and an "effective" alternating-current density of the same value.† the total current density, as found with the hot-wire instrument, is $\sqrt{1250^2 + 1250^2} = 1767$ amp per square meter.

In this case the direct-current voltage at the terminals of the cell, measured by a direct-current instrument, would be about 1 volt and the total voltage about 1.4 volts. This gives an alternating-current voltage of 0.9 volt.

In the design of the dynamos it is best to figure on 1.3 volts as the maximum direct-current voltage, and on 1 volt as the maximum alternating-current voltage per cell. Since both dynamos are connected in series their armatures must be dimensioned so that they can stand the heating effect of the maximum total combined current. Within the usual limits of frequency (that is, for frequencies below 50 periods per second) the value of the frequency has practically no effect on the results obtained with the alternating current.

The most suitable value of the current density and voltage depends, of course, on the composition of the gold or gold alloy. If the gold contains less silver than 10 per cent, it is possible to increase the direct-current density somewhat and to decrease the ratio of alternating current to direct current slightly. If the gold contains much more silver, either the direct-current density should be diminished or the alternating-current density increased.

Otherwise, the process is the same as formerly carried out. In general, gold chloride solutions are used containing at least 3 per cent of hydrochloric acid and heated to 60° C. or 70° C. If, however, time is not of great importance, so that a direct-curreut density between 500 amp and 1000 amp per square meter can be employed, it is possible to use a gold chloride solution containing only 0.7 per cent to 0.8 per cent of hydrochloric acid and heated to 60° C. to 70° C., or it is not necessary to heat the solution at all if 3 per cent of hydrochloric acid is added.

Instead of hydrochloric acid, or part of it, chlorides which form double salts with gold chloride, for instance, sodium chloride, can be used. As previously described, thin rolled gold sheets are used as cathodes and gold is supplied to the electrolyte periodically in form of gold chloride to make up for the loss of gold from it. If gold rich in lead is refined, sulphuric acid is added to the electrolyte in quantities equivalent to the free hydrochloric acid present.

Rutgers Chemistry Building.—The contract for the new chemistry building of Rutgers College has been awarded and the work is under way. The building will be of brick with terra cotta trim, and will harmonize architecturally with the engineering building which was completed slightly over a year ago. On the first floor will be a large lecture room and three classrooms. On the second floor will be a qualitative and a quantitative laboratory, a laboratory for work in electrochemistry and one for water analyses, professors' private offices and laboratories, and a supply room. In the basement will be the laboratory for the elementary work of the freshman year, a stock room and the necessary heating and ventilating apparatus for the building.

---

*The direct current i_d does not change in time, while the alternating current does change periodically. The simplest kind of wave form is a sine wave; we may, therefore, write the instantaneous value of the alternating current $= i \sin(2\pi nt)$ where i is the maximum value of the current, t is the time in seconds and $1/n$ is the period in seconds. It will be seen that the current is zero at the moments $t = 0$, $1/2n$, $1/n$, while it reaches the maximum $+ i$ at the time $t = 1/4n$, and the minimum $- i$ at the time $3/4n$. The arithmetic mean value over a whole period is zero. As this determines the electrolytic action (since according to Faraday's law the deposit is proportional to the product of time and current), the total electrolytic action caused by an alternating current during one full period is zero; in other words, all the electrolytic deposit obtained during the first half of the period (while the current has always the same direction), is being undone during the next half period (while the current has the opposite direction). It is different, however, with the Joulean heat produced by an alternating current because this is proportional to the square of the current; its value during one half period is the same as during the next half period and the two add together. It is, therefore, customary to define the "effective value" of an alternating current (such as indicated by a hot-wire ammeter) as the square root of the mean square of the current. That is, the mean is determined of the squares of the instantaneous values of the current at all moments during a whole period; this gives the "mean square" of the current; by taking the square root, we get the "effective current." It can be easily shown by mathematical calculation, that if i is the maximum value of the current as above the effective value is $i/\sqrt{2}$; this effective value is designated in the text with i_a. With a pulsating current, obtained by the superposition of a direct current i_d over an alternating current $i_a\sqrt{2} \sin(2\pi nt)$, hence of effective value i_a, we can also form the two mean values over a full period. The arithmetic mean, which determines electrolytic action, is simply i_d (as though the alternating current was absent). The "effective" mean value, which is found by a hot-wave ammeter, is $I = \sqrt{i_d^2 + i_a^2}$ as stated above in the text.—Editor.

†If the direct-current density is 1250 amp. per square meter and the effective alternating-current density is also 1250 amp. per square meter, the maximum alternating-current density is $1250\sqrt{2} = 1767$ amp. During that half period of the alternating current, during which the latter has the same direction as the direct current, a certain electrolytic work will be done by the sum of the two currents. During the other half period, some more electrolytic work of the same nature will be done as long as the instantaneous value of the alternating current is below 1250 amps. But during that portion of time, during which the alternating current rises from 1250 amps. to its maximum (1767) and falls again to 1250 amp., the electrolytic action is opposite: what was anode is now cathode and inversely; part of the electrolytic work formerly performed will now be undone. The total electrolytic work performed by the pulsating current (weight of gold refined and deposited) during one full period will be just the same as though we had only a direct current of 1250 amp. But the electric power consumption is, of course, that of both the direct current and the alternating current together.—Editor.

The Use of Carbonaceous Filters in the Smelting of Zinc.*

BY C. O. BANNISTER.

The process described in this paper is the outcome of experiments commenced by Evan H. Hopkins some ten years ago.

These experiments were begun with the object of obtaining zinc free from lead as a product when smelting zinc materials containing lead.

In the first experiments a mixture of zinc oxide, lead oxide and carbon was placed in a cavity in a carbon block fitted with a carbon lid, the carbon block was then introduced into a muffle, and the zinc was distilled over into a receiver. As the result of the experiment, zinc practically free from lead was obtained, and the lead was found in a lump inside the carbon block.

The first idea as to the method of applying this principle on the large scale was to use a modified retort such as that

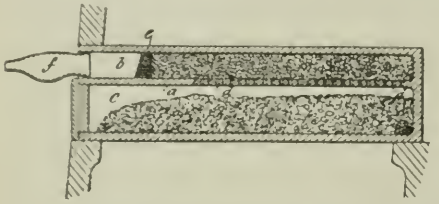

FIG. 1.—FIRST FORM OF RETORT, WITH CARBONACEOUS FILTER.

shown in Fig. 1, and to pass the products of distillation through an incandescent filter of carbon. In the figure given the retort is shown to be divided into two portions by means of a partition, *a*, made of clay, and perforated with small holes, *d*.

The upper chamber, *b*, was filled with fine lumps of charcoal or coke, well pressed together, and kept from falling apart by means of a movable and perforated stopper, *c*. After the ore mixture had been placed in the chamber, *c*, this portion was closed and heated. During the process the zinc distilled through the carbonaceous filter, and was condensed and collected in the receiver, *f*, in the ordinary way.

From the beginning it was evident that in order to make this process a commercial success it would require considerable modification and simplification, and experiments were carried out with a view of making the condenser also take the part of a

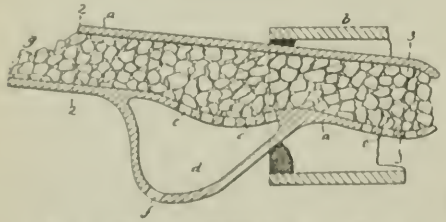

FIG. 2.—MODIFIED CONSTRUCTION OF CONDENSER.

filter. After a large number of experiments the form shown in Fig. 2 was adopted. This consisted of a large condensing chamber divided by means of a perforated partition into a condenser proper and a receiver, *d*.

The upper portion or condenser was filled with small pieces of carbon in the form of charcoal or coke, and the whole was placed sufficiently far into the zinc retorts to insure that the carbon filter should attain a sufficient temperature to prevent choking. This form of condenser was modified slightly from time to time and was used in actual practice, the results obtained being compared with those obtained from retorts fitted with the ordinary condenser. The experiments were made with much care, particular attention being paid to weight, charge, analyses, and like details, and the whole operation was watched for 24 hours without intermission.

During these experiments, which were made in furnaces treating galvanizer's dross, the following points were clearly brought out:

1. The zinc obtained from the Hopkins condensers was invariably purer and freer from lead.

2. No oxide or zinc fumes emanated from the Hopkins condensers.

3. The zinc flame, always observable at the mouth of ordinary condensers, was absent when the Hopkins condensers were used.

4. By the use of the Hopkins condensers a larger proportion of the spelter contained in the charge was obtained as metal.

5. It was established that the hotter the furnace the greater

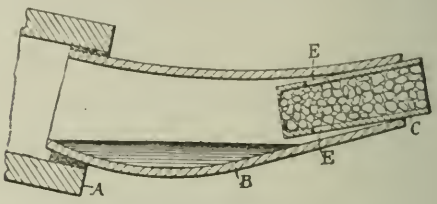

FIG. 3.—CONDENSER CONSTRUCTION.

was the yield of metal by the Hopkins condensers, whereas with the ordinary condensers higher temperature means increased zinc flame, fumes and loss.

It will thus be seen that the above series of trials was most fruitful in indicating the practicability of preventing the zinc fumes which are always a cause of annoyance in the neighborhood of zinc works, and at the same time the prospect of obtaining thereby a greater yield of zinc.

It was, however, considered still possible to simplify the construction of the condenser so as to make it much cheaper. To this end the whole of the central portion of the condenser (Fig. 2) was eliminated, but exactly the same principle was retained in the new arrangement. In this case the condenser, *B*, as ordinarily used in spelter works, or a slightly modified form thereof, may be used, into which is inserted, at the inner end, a carbonaceous filter to keep back the lead, and, at the outer end a tube, *C*, packed with carbon. This combined form is to be used when the aim is to obtain a high quality of zinc as well as the subsequently mentioned advantages, but when it is merely desired to eliminate the objectionable fumes

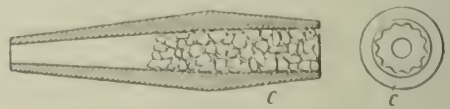

FIG. 4.—CARBONACEOUS FILTER

and to obtain a higher extraction, the outer tube only need be used as indicated in Fig. 3.

Various forms of fire-clay tubes have been employed to contain the carbonaceous filter; to illustrate one of these Fig. 4 is given, which shows a double conical tube, having one end, namely, that which enters the condenser, made with longitudinal corrugations internally. By reason of these corrugations the choking of the tube is prevented during work, but the escaping gases, etc., come into contact with the hot carbon. The tube at present in use consists of a cylinder about 8 inches long, of 3½ inches external diameter, and 2 inches internal diameter, and has flanges to keep in the coke; it also

*A paper presented before the Institute of Metals at the annual general meeting held in London on January 10, 1912.

has a small hole running through its wall for the insertion of a pricker when found necessary during the process.

It will be seen from the foregoing that the process, beginning with the object of making lead-free spelter only, has been gradually modified and simplified, and in its present form embraces the three following objects:

(a) Manufacture of pure spelter.
(b) Prevention or reduction of zinc fume.
(c) Obtaining of higher yields.

(a) Manufacture of Pure Spelter.

Since Mr. Hopkins first demonstrated the possibility of obtaining pure zinc by passing the vapors from zinc retorts through incandescent carbon, this process has received considerable attention from zinc smelters, and it is now an accepted fact that the operation may be carried out economically and effectively.

To what extent the process will be applied to ordinary zinc smelting is at present unknown, as the demand for zinc of a very high standard of purity is somewhat limited; but there is no doubt that it will be adopted in the treatment of materials containing too much lead for the production of commercial spelter direct, that is, without a subsequent refining operation.

The fact that a carbonaceous filter behaves as a strong reducing agent puts it far in front of filters composed of materials which do not possess this property, for its presence in an incandescent state insures that the whole of the metallic vapors shall be and remain reduced, and at the same time any carbon dioxide passing out with the gases will be reduced to carbon monoxide.

As the amount of reduction that takes place in the filter requires only a little carbon, the consumption of the carbon of the filter is small; but this consumption is advantageous, as it tends to keep open the filter and lessen pressure due to the deposition of lead, etc.

In the actual working, coke has proved more suitable than coal for the filter, and at the same time it is more economical. In fact, experiments have demonstrated that coke is the best material for this purpose, and it should be of a light, porous variety, not dense, and should contain only a small quantity of volatile matter.

As to the results obtained, the following illustrates the purity of the zinc:

From galvanizer's dross the spelter contained 99.86 per cent zinc from the Hopkins filter as compared with 98.75 per cent from an ordinary condenser working on the same charge.

As to whether the process will be used to any extent for the treatment of zinc-lead concentrates, time alone will decide, for details other than the production of pure zinc have here to be taken into account, such as the manner in which the charge attacks the retorts and other parts of the apparatus. For rich zinc concentrates containing smaller quantities of lead, however, there is no doubt that the process is most suitable, as not only can pure zinc be obtained but a considerable quantity of the lead can be recovered on treatment of the filters.

Some comparative tests have been carried out on the treatment of Broken Hill middlings, and not only was a purer zinc obtained from the Hopkins filters, containing 99.6 per cent zinc as compared with 96.5 per cent from ordinary condensers, but the yield of metal averaged over 20 per cent more when such filters were used.

(b) Prevention of Zinc Fume.

In view of the necessity for some cheap, simple and effective method for preventing the formation or reducing the amount of fume during zinc smelting, the Hopkins outer cork is of very great importance, for it is found to be most efficient as a fume preventer.

The presence of this cork or nozzle, packed with carbon, acts in almost a magical manner, keeps back practically all trace of zinc fume, and gives to the gas burning at the ends of the nozzle a flame similar to that obtained during the burning of carbon monoxide gas. The inspection of a zinc furnace fitted partly with ordinary condensers and partly with Hopkins condensers is most surprising and instructive, and the absolute efficiency of the nozzles as now used is at once clearly demonstrated. The presence of the hot carbon at the outside end of the condenser or pipe seems to affect the whole condition of the condenser, for even when put in so loosely that part of the flame escapes between the carbon-containing nozzle and the mouth of the condenser, this flame is also practically free from zinc. From the time the gas in the coal finishes until the last tap, the whole condition of the furnaces supplied with nozzles is improved.

During the periods of tapping the zinc the fumes are very much less, for only two or three condensers are uncovered at a time, and as tapping proceeds, the nozzles as removed are put into the condensers already tapped. The workmen also notice further advantages, for the metal in the condensers fitted with nozzles is hotter than the metal in ordinary condensers, and will more readily melt up "drippings" of spelter; also skulls of metals are never present in the condensers.

The Local Government Board have taken great interest in all methods suggested for the prevention of the escape of zinc fume, and four Government inspectors have examined the Hopkins process in operation in Swansea, and were much impressed by what they saw. The following are extracts from the Annual Report on Alkali, ..., Works, 1908:

Page 90: "In a previous report (42d, page 64) I have mentioned that trials were being given to the Hopkins nozzle, one of the variants of this type of appliance, and with some amount of success. The results of trial have led to simplification in design and construction without, I am informed, any sacrifice of efficiency. It is now believed that not only can spelter of greater purity be obtained, but also in substantially increased yield as compared with other retorts working under the same conditions in the ordinary way without the nozzle. If working for quality, *i. e.*, freedom from lead, the vapors from the retort pass through an additional incandescent chemical filter suitably formed in the furnace end of the condenser. At the outer end of this condenser another appliance aims at reducing any zinc oxide formed in the condenser from access of air to the vapor of zinc. From recent observation of two contiguous benches of thirteen retorts each and comparison of escaping gases near the time of first tapping, *i. e.*, at the period of the greatest liability to evolution of fume, I am convinced of the possibility of success in preventing this in very great measure. It was easy to compare the fume escaping from similar benches not provided with the nozzle, and in the same condition, as to charge and equipment."

Page 180: "Several experimental efforts are at present being made to reduce the impalpable white cloud of oxide of zinc which escapes from the retorts during the smelting operation.

"The 'Hopkins Condenser' is being tried at Swansea with encouraging results. The condenser, which is provided with what may be called a chemical cork, consisting of coke, is adapted to the retort or pot commonly in use.

"By this means the inventor endeavors to prevent the formation of zinc oxide during distillation, thereby obviating the escape of the metal as an oxide seen in the familiar white fumes, inseparably associated with the manufacture of spelter or commercial zinc. At the works referred to, these condensers showed a remarkable diminution in the escape of fumes, and we are informed that there is a substantially increased yield of metal as compared with that obtained by the ordinary process of smelting."

(c) Higher Yields.

The absence of fumes which is noticed when the Hopkins nozzles are in use on zinc retorts should naturally lead to less loss by oxidation and therefore to higher yields of metal.

This has proved to be the case when the process is worked under proper conditions, and the results of continued comparative tests have always shown the Hopkins nozzles to yield more metal. It must be remembered, however, that in the extraction of zinc many factors must be considered which are likely to upset results, such as the breaking of retorts, unequal heating of the furnace, etc. The first comparative tests for yield were carried out on contiguous bays of thirteen retorts, in a two-tiered, gas-fired zinc furnace; further bays of thirteen retorts were added until the whole of one side of the furnace was worked against the whole of the other side.

As the charges in all cases are absolutely similar, only the weight of metal actually obtained need be taken into account.

Table I shows the results of eighteen weeks' continuous work, and it will be noticed that during this run only one week showed a decrease in the amount of spelter yielded by the Hopkins nozzles.

TABLE I.—RESULTS OF FIRST EXTENDED SERIES OF TESTS.

Table II shows the results of the first week's work on a recently repaired furnace, one side being worked against the other.

It must be remembered that in the ordinary method of working the zinc furnace the yields vary very considerably from day to day in different furnaces and even in the two sides of one furnace, and therefore it is not to be expected that occasionally for one day, or even in the case of the average for a week, the yield should apparently be less when the condensers are used. On examination of the tables given it will be noticed that there is not only a distinct advantage from the point of view of yield, but also that the percentage variation and the greatest deviation from the mean result are less with the Hopkins nozzles, points which are both in favor of this method.

TABLE II.—DETAILS OF ONE WEEK'S WORK.

Date	Ordinary: No. of pipes	Ordinary: Yield Cwts.	Ordinary: Yield Qrs.	Ordinary: Yield Lb.	Ordinary: Average yield per pipe lb.	Hopkins: No. of Pipes.	Hopkins: Yield Cwts.	Hopkins: Yield Qrs.	Hopkins: Yield Lb.	Hopkins: Average yield per pipe.	Increase by Hopkins Per cent
Oct. 7	75	12	1	5	17.51	13	2	0	21	18.[illegible]	3.0
Oct. 8	75	11	0	14	15.49	75	11	1	21	17.45	12.6

Oct. 11	78	13	2	25	18.08	78	13	2	1	19.15	7.4
Oct. 12	78	11	2	1	16.62	74	13	1	6	19.62	18.[illegible]
1923	75	12	1	10	18.43	—4.1	Oct. 13			28	11	1	10		

In examining the tables given it will be noticed that there is not only a distinct advantage from the point of view of yield, but also that the percentage variation and the greatest deviation from the mean result are less with the Hopkins nozzles, points which are both in favor of this method.

It is estimated that the corks or nozzles will be made at a cost of 4s. to 5s. ($1.00 to $1.25) per 100, and that filling for a furnace of 150 retorts will cost 2s. to 2s. 6d. (50 to 62 cents) per day.

Summary.

1. By means of the Hopkins carbonaceous filters and corks or nozzles the following three advantages may be obtained in zinc smelting: (a) Pure spelter. (b) no zinc fume. (c) higher yield.

2. The process may be applied to any already existing retort zinc furnace, no constructive alterations being necessary.

3. Only a slight modification of the condenser is necessary, this consisting in the widening of its mouth.

4. The process is absolutely simple to work.

5. The metal is hotter in the condenser, and no skulls of solid zinc are formed.

6. Not only is a higher yield obtained, but also a more steady yield, less fluctuation taking place when the nozzles are in use.

Kirchhoff Luncheon.

Some 130 friends of Mr. Charles Kirchhoff assembled at a luncheon at the Engineers' Club, New York City, on Sunday, Jan. 16, to express their admiration for him as editor and man, on the occasion of his recent retirement from the editorship of *Iron Age* which had extended over 30 years.

CHARLES KIRCHHOFF.

Mr. Philip T. Dodge, president of the Engineers' Club, acted as toastmaster.

Mr. T. C. Martin read letters from many who were unable to be present, among those who had sent expressions of their high esteem for Mr. Kirchhoff were Andrew Carnegie, James Douglas, John Hays Hammond, James H. McGraw, J. Langeloth, John Birkinbine, and W. H. Wiley.

Dr. R. W. Raymond, secretary of the American Institute of Mining Engineers, made one of his delightful characteristic speeches. He referred to the contest for the secretaryship of the Institute in 1885, when both Raymond and Kirchhoff were candidates. This contest became the foundation of a long, firm, and undisturbed friendship.

Mr. George W. Cope, editor of *Iron Age*, spoke eloquently as the representative of the old associates of Mr. Kirchhoff in David Williams Company and presented to him a French bronze by Picault, "La Source du Pactole."

Mr. Kirchhoff's reply, which showed clearly how much he was moved, was as modest and sincere as the man himself.

The final speakers were President Henry S. Drinker, of Lehigh University, and Mr. John Fritz, the veteran iron master, who had come, in spite of his 87 years, from Bethlehem, Pa., to express his regards for his friend of many years.

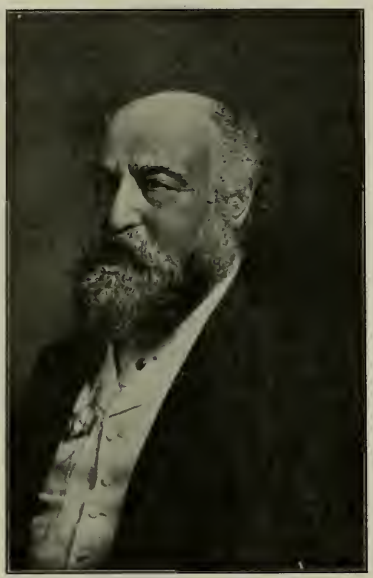
"Auld Lang Syne," played by Mr. Geo. H. Guy, marked the conclusion of the luncheon, which was a modest yet most expressive tribute to one of the greatest, ablest, and most influential editors which the engineering press of any country has ever had.

Mr. Kirchhoff has sailed on a trip to the West Indies.

The Late Dr. Ludwig Mond.

Dr. Ludwig Mond, who died in London before the sun rose on Saturday, December 11, was one of the most successful industrial chemists of his time—a man who owed his success to a rare combination of business ability, capacity for research and energy. The public knew him as one of the founders of the alkali firm of Messrs. Brunner, Mond & Company, as the inventor of the Mond gas and of a nickel process, and as a generous donor to many scientific institutions. We take this account of his life from the London *Engineering*.

Ludwig Mond was born nearly 71 years ago at Cassel, then the capital of the Electorate of Hessen, which since 1866 has formed part of the Prussian kingdom. His father, a merchant, had him trained at the Polytechnic Institute of Cassel, and later at the universities of Marburg and Heidelberg. Recommendations from so distinguished professors as Hermann Kolbe and Robert Bunsen stood young Mond in good stead when, after having held appointments in two German chemical works, he came to England in 1862. He found employment at Widnes in the chemical works of Messrs. Hutchinson and Earle, and there he was able to show that a method patented by him for recovering the sulphur, which had so far been wasted, in the black ash of the Leblanc process was technically applicable; this method was adopted in Newcastle and Glasgow.



DR. LUDWIG MOND.

Returning to the Continent, he joined Ernest Solvay, of Charleroi, near Brussels, the inventor of the ammonia-soda process. Having founded Solvay works at Utrecht, he returned to England in 1867, acquired the Solvay patents for England and started, in 1872, works of his own at Winnington, near Northwich, over the Cheshire salt deposits, with Mr. (now Sir) John Brunner, whose acquaintance he had made in the Hutchinson family, as partner.

It was a risky undertaking to compete in England against the Leblanc process, where it had been elaborated into one of the most perfect cyclic processes known. The raw materials of the Leblanc process are salt, sulphuric acid, coal and lime—all relatively cheap. In the ammonia-soda process the brine is saturated with ammonia—an expensive material—and then with carbonic acid, the crystallizing bicarbonate of soda being afterwards converted, by boiling or by calcination, into ordinary carbonate of soda. The Leblanc process yields hydrochloric acid as a by-product; in the Solvay process the chlorine combines with calcium to form chloride of calcium, and the enormous quantities of this compound remain practically waste heaps up to the present time. A good deal of the success of the new firm was due to the improvements which they effected in the recovery of the ammonia (by means of quicklime). When they started they knew that Dyar and Hemming had tried an ammonia-soda process, likewise in Cheshire in 1838, and had failed, and that the struggle against the giant Leblanc was considered hopeless. After 1875, however, their success was assured. In recent years new and formidable rivals have arisen in the electrolytic alkali processes. To meet that rivalry new efforts were made to utilize the calcium chloride; some of it is now treated with zinc oxide and transformed into zinc chloride, which on electrolysis yields a very pure zinc, and the calcium chloride in itself makes a fair road dressing.

The sight of the enormous waste of gases in his Winnington boilers, it is said, suggested to Dr. Mond the study of the producer-gas problem. He succeeded in burning cheap bituminous slack by the aid of an air-blast and steam and in absorbing the ammonia evolved by dilute sulphuric acid, thus obtaining a fair producer gas and, in addition, ammonium sulphate as a by-product, whose value, unfortunately, decreased, owing to this and other new sources of production. Mond gas is now chiefly made at Dudley Port, in Staffordshire.

The same researches led him to another discovery. The producer gas contains hydrogen, and when, 20 and more years ago, the problem of galvanic gas cells for the direct generation of electricity from coal—not by way of boilers, steam engines and dynamos—excited general attention, Dr. Mond attempted to isolate the hydrogen from the other constituents of the producer gas. For this purpose he conducted the gas over various compounds and metals, and observed that nickel was taken up by the gas; it was the carbon monoxide which formed nickel carbonyl under certain conditions of temperature and pressure, and this carbonyl is again decomposed at 200° C. and deposits a mirror of pure metal. The new compound was first described by Dr. Mond in 1890, and the Mond Nickel Works at Clydach, near Swansea, are now converting part of the nickel ores from the famous Canadian mine at Sudbury, or the matter smelted there, into a very pure nickel.

Years were, of course, required to work out this process, and Dr. Mond had the assistance of many able chemists and engineers in his researches and undertakings. It would be wrong, however, to regard Dr. Mond mainly as the managing director and commercial chief. Dr. Mond was himself a remarkably capable and painstaking research chemist. During the last five years his health caused his friends much anxiety. About a year ago he recovered wonderfully, and he ought to have spared himself. Always busy and hard at work with the general management, however, he took the study of the carbonyls up again, and succeeded in preparing carbonyls of iron, cobalt, molybdenum and ruthenium, which are stable only at very high pressures—450 atmospheres in the last-mentioned case. He announced these discoveries at the International Chemical Congress, which met in London in May and June last. When he fell ill again this autumn grave fears were entertained.

Since 1857 Dr. Mond has been domiciled in England. The year previous he married his cousin, Miss Frieda Loewenthal. His winters he liked to spend in Italy, and his house, the Poplars, in Avenue Road, near Regent's Park, in which he died, is well stocked with masterpieces of the early Italian school. His friendship with the great Italian chemist, Stanislao Cannizzaro, induced him to found a Cannizzaro prize.

Having long supported low-temperature research in the Royal Institution of London, at whose lectures he was a familiar figure, he established the Davy-Faraday Research Laboratory in the house adjoining the Royal Institution in Albemarle Street, and endowed it liberally. The laboratory was opened by the King in 1896. His donations to the Universities of London, Cambridge, Manchester and Liverpool, the Lister Institute of Preventive Medicine, and the association which aims at creating a Chemische Reichsanstalt, a sister institute to the Physikalisch-Technische Reichsanstalt in Char-

lottenburg, were on a grand scale; and it was due to his munificence that the Royal Society, which elected him a Fellow in 1891, was enabled to start its international catalogue of scientific papers. Dr. Mond held honorary degrees from the Universities of Padua, Heidelberg, Manchester and Oxford. One of the honors he valued most highly was his election, in 1898, to the Athenæum Club under the rule which empowers the Council to admit distinguished men of science.

Dr. Mond leaves two sons—Dr. Robert Mond, a Cambridge scientist, and Arthur M. Mond, M. P. for Chester.

* * *

By Dr. Mond's will he leaves $300,000, payable free of legacy duty, on the death of his wife, to the Royal Society of London. The income from this bequest is to be devoted to the assistance of research in the natural sciences along various lines. A like sum for like purposes is also bequeathed to the University of Heidelberg.

In addition to other bequests, Dr. Mond left a fund in the care of six trustees to be chosen by the directors of Brunner, Mond and Company, three trustees to be taken from among the workmen of that firm. The income of the fund is to be used to assist or pension aged or disabled employees of the company. In the event of the dissolution of the company the money will go to the poor of Northwich, where the chief works are located. Another $100,000 is also bequeathed to the city of Cassel, Germany, for charitable purposes. The will then disposes of the collection which Dr. Mond had got together with the advice of Dr. Richter. The collection, which is not large in point of number, was formed slowly, Dr. Mond hardly ever buying more than two or three pictures a year since he made his first acquisition, in 1892.

A schedule annexed to the will gives the names of fifty-six pictures, the list being headed "Pictures for the National Gallery." On the death of Mrs. Mond the trustees of the National Gallery may select at least three-fourths of the works named in this list, or may make up the number, forty-two, from his remaining works of art. These pictures are to be kept together in a room or rooms in the National Gallery under the name of the Mond Collection. He leaves his wife power to bequeath not more than twelve of his pictures to any person she may think fit, but they may not be taken from those selected by the National Gallery.

All the remainder of the pictures are to be given, either singly or in lots, to museums or institutions in Europe or Canada, each one to be marked as the gift of Dr. Mond, but without any restriction as to their being kept together unless at least forty go to one institution. Dr. Mond hoped that the proper authorities will consider the pictures given to the National Gallery as of national interest, and remit all duties that might be levied on the bequest.

The Late Ottokar Hofmann.

We regret with sorrow the death of Mr. Ottokar Hofmann, the distinguished metallurgist, which occurred on Dec. 24, 1909, at Kansas City, Mo. Mr. Hofmann's last work was done in Mexico from 1907 to 1908, and during the course of it he encountered hardships which seriously injured his health. Over six months ago he suffered from a complete breakdown, and from then up to the time of his death he was confined to the house.

Mr. Hofmann was born in 1843 at Rusberg, in Austria-Hungary, and educated at the Realschule and Polytechnic Institute in Vienna, and the Bergakademie at Freiberg, graduating from Freiberg in 1867.

In 1867 Mr. Hofmann came to the United States, entering the assay office of Curtis Kunzel, in San Francisco, as a partner. This was his first venture.

Mr. Hofmann has largely been identified with leaching processes for the extraction of gold and silver from ores. In 1868 he erected at La Dura, Sonora, Mexico, the first lixiviation works operated in North America, following up this success by the construction of other works at La Trinidad and San Marcial, Sonora, and Trinufo, Lower California. He has served as metallurgist for various amalgamation and chlorination mills in Nevada and California, and since 1880 was engaged in the practice of hydrometallurgy.

In 1895 Mr. Hofmann took charge of the leaching department of the Consolidated Smelting & Refining Company, at Argentine, Kan., and in 1897 he displaced the Hunt and Douglas process then in use by a process which freed copper sulphate solutions in one operation from iron, arsenic, antimony and other impurities. Mr. Hofmann further became consulting chemist for the American Smelting and Refining Company, and consulting metallurgist for the Avino mines of Mexico and chemical director of the United Zinc and Chemical Company, of Kansas. Mr. Hofmann has written a valuable treatise on the hydrometallurgy of silver.

Nitrates in Norway.

The Norwegian industry of manufacturing air nitrates for fertilizer is undergoing rapid extension involving the expenditure of nearly $15,000,000, according to the British consul at Christiania.

Two processes for the manufacture of this product are in use in Norway. The older of the two is the Birkeland-Eyde process, previously described (Vol. VII, page 304), and the newer is that of the Badische Company, also dealt with in these columns. (Vol. VII, page 245.)

Regarding the details of the Norwegian activity we take the following summary from the report of the British consul:

Up till now about $6,000,000 has been expended on the works at Notodden and Svaelgfos and the power stations under construction at Rjukan and Vamma. When all the works are completed, at the end of 1910, $14,600,000 will have been spent. A great point in connection with the development of this industry is that the opportunity has now arisen of opening up several industries in connection with the manufacture of nitrates, such as nitric acid, nitrate of ammonia, nitrate of potash, also sodium nitrate, which last is already being manufactured.

The Nobel syndicate, in conjunction with the Birkeland and Eyde Company, is now concentrating the weak acids, with the assistance of the gas furnaces, to an acid of such percentage as to become an article of transport, and further opportunities have thus been opened for export trade, especially from works with water-power that are situated near the seaboard.

It is of interest to note that no coal is used in the production of saltpeter or other products here referred to. It is stated authoritatively that there is no probability for many years to come that the sale of saltpeter produced by the method practiced at the Notodden and Rjukanfos works will be disturbed by the competition with Chile saltpeter on the question of price.

When the Rjukan Falls works are fully completed, they and the Notodden works combined will represent 240,000 hp. with a production of saltpeter representing an export value of $6,164,000.

At some not very far distant time it is not improbable that the waterways and loughs between Skien and Notodden may be increased to such size as to allow seagoing vessels to load up at Notodden. Plans have already been worked out and are under consideration in connection therewith. At present everything has to be lightered to and from Skien.

The value of the output of nitrates in Norway in 1908 was about $536,000, and the total expenses amounted to $402,000.

The following are the companies that are producing, or will shortly produce, saltpeter from the air:

(1) The Norsk Hydro-Elektrisk Kvaelstof Aktieselskab, Christiania, who are the owners of the Notodden Saltpeter-

fabrikker, the power of which (35,000 hp) is supplied from the Svaelgfos. The capital of the company, which is French, is $7,890,000.

(2) The Vammafos (Vamma Falls) Company, whose saltpeter works are now under construction. This company is a separate company, but half of its shares are said to be owned by the Norsk Hydro-Elektrisk Kvaelstof Aktieselskab; some of the preference shares are in the hands of Norwegians. The amount of the capital cannot be stated.

(3) The Rjukanfos (Rjukan Falls) Company, whose saltpeter works are also in course of erection. The capital of the company, which is one-half French and the other half Scandinavian and German, is $3,376,800. This capital has been furnished by some of the shareholders of the Norsk Hydro-Elektrisk Kvaelstof Aktieselskab and of the Kraft Aktieselskab, but the company is an independent one.

(4) The Matre and Tyin waterfalls are owned by the Norsk Hydro-Elektrisk Kvaelstof Aktieselskab and by the Kraft Aktieselskab, but the companies formed in connection with these falls are two separate companies with separate administrations. Electrotechnical works will probably be erected at both falls.

(5) Christianssands Elektrokemiske Aktieselskab, which is the property of the Badische Anilin und Soda Fabrik, Ludwigshafen, and has a capital of $53,600.

The Chemist's Place in Power Economy.

Industrial progress depends no longer on *"increased* production" only, but on "increased *efficiency* of production." Nowhere more than in the production and transmission of power are there greater opportunities for improvement for the saving of time, and labor, and money. That the chemist ought to take the foremost part in solving the problems of power efficiency is the argument convincingly set forth in a paper read at the recent convention of the American Chemical Society by Mr. ARTHUR D. LITTLE, of Boston.

Mr. Little made a vigorous presentation of the chemist's special qualification for dealing with problems of power, which should no longer be monopolized by the mechanical engineer. It is sometimes forgotten that chemical science deals with energy no less than with matter. In fact, chemistry as a science, began with the recognition of the principles, materials, and products of combustion. But chemists have allowed the mechanical engineer to usurp many things which properly come much more directly within their own province.

The combustion of coal is a typical chemical process. The selection of the most efficient coal and the determination of the conditions necessary for its most efficient combustion are essentially chemical problems. Chemical problems also are those arising in the manufacture of producer and illuminating gas, their utilization in gas engines, the development of power from the waste gases of the blast furnace, the adaptation of conditions to the proper handling and burning of peat, lignite, and waste coal, the thermometric exploration of coal piles to forestall spontaneous combustion, smoke abatement, the control and improvement of fireroom conditions by draft regulation, flue gas analysis, temperature measurements and even the placing of firemen on the bonus basis. Taking power-plant practice and the conditions of coal purchases as they stand, the properly equipped chemist should be able to increase the efficiency of power production from 5 per cent to 30 per cent.

The analysis of boiler compounds as an end in itself presents little to excite enthusiasm, but when such analyses become the means of saving $3,600 a year in the power plants of a single company they take on a new and larger aspect, not only in the mind of the chemist, but in the mind of the chemist's client.

The chemist who attacks the problems of power production will not hesitate to go outside the laboratory and take his property wherever he finds it. He will conduct boiler and engine tests, study the efficiency of grates and stokers, familiarize himself with the marvelous promise of the low-pressure turbine as an agent in efficient power production. While straining every resource of his science to produce steam economically by the combustion of coal, is it common sense for the chemist to stop there in ignorance of the fact that the efficiency of that steam can be increased at once from 25 per cent to 100 per cent by coupling a turbine to the exhaust?

The distribution of power-supplies problems no less directly within the province of the industrial chemist. He may begin with the analysis of lubricating oils. He proves his own inefficiency if he stops there. He must inform himself regarding the market prices of oils used elsewhere for similar service, the adaptability of the oils in question to application to the bearing by soaked waste, sight feeds, or gravity cups. He must be prepared to interpret his analysis in terms of practice and to follow the oil through the plant in order to prescribe conditions which shall keep down waste. There are few plants in which the industrial chemist working along legitimate lines cannot save from 20 per cent to 60 per cent of the entire lubrication account, while the oil analyst has to his credit merely a few figures which his client probably fails to understand.

The efficiency and life of bearing metals varies over an extraordinarily wide range. Some are merely the refuse from type foundries, others are so carefully adapted in their composition to the requirements of particular service as to show an efficiency 15 times or more as great as that of inferior material. Here, again, the mere analysis means little, the practical question is: "Which is the more efficient metal under the conditions imposed by practice?"

Much additional might be said regarding the opportunity before the chemist when any material concerned in power transmission is the subject of his study, whether it be leather, rubber or canvas belting, belt dressings, insulating material, trolley wire, trolley cars or trolley wheels. In every case it is within his power to create a new standard of efficiency.

Notes on Metallurgy and Chemistry in Great Britain.

(From Our Special Correspondent.)

Institution of Mechanical Engineers.

At the meeting on December 17 papers were read on "Mild Steel Tubes in Compression and Under Combined Stress," by Mr. W. Mason, and on "Compound Stress Experiments," by Prof. C. A. M. Smith.

The discussion was opened by Mr. J. J. Guest, who said that he thought the authors had not explained sufficiently fully the aim they had in view. He said so, because, after reading a similar paper himself, he found that many in his audience had been unable to acquire a precise idea of the ground he wished to cover. When a specimen was put in an ordinary testing machine it would break at a certain number of pounds per square inch; and a tension member in a bridge could be strictly compared with the result of such a test. In the case of mild steel in an unstayed boiler there was a hoop-like stress around the boiler, as well as the longitudinal stress, and the material was consequently subjected to tension in the two principal directions at right angles to each other. Experiments in ordinary testing machines did not give any evidence as to the second tension affecting the capacity of the material in respect of the first tension. The experimenters were trying to solve the following questions: (1) Could the effect of tension on the resistance of the material be ascertained? and (2) Would the second stress diminish the material's capacity of resistance? In the case of the crankshaft referred to by Professor Smith the second stress was of an opposite nature to the first; that is, one was a stress of tension and the other a compressive stress, or vice versa.

Experiments which Mr. Guest himself had carried out had satisfied him that the shear stress was the chief factor in the case of ductile mild steel, but the authors had extended their

researches to new ground. He would first criticise Mr. Mason's experiments. He did not think that two of the figures represented a perfectly fair view of matters. Mr. Mason had tested his material in axial tension, and found it gave a certain point, *A*. He had also made experiments corresponding to the boiler plate and had applied equal tension to test pieces both longitudinally and laterally, thus getting another point, *B*, as the yield point for combined axial and hoop tensions. A new tension in a direction at right angles to the first would not lower the capacity of the material to resist the first tension. In dealing with stresses combining tension and compression, Mr. Mason had first subjected the material to compression, and ascertained the yield point. Then he had applied a certain tension in combination with an equal stress of compression, and found that he could not apply much more than half the previous stress. The stress in the material in such cases was purely shear stress, and as a consequence the second stress had a great effect on the resistance of the material to the first stress. Mr. Guest's further remarks on Mr. Mason's paper are not intelligible without the aid of a diagram.

Professor Smith, as well as others, had criticized the use of tubes for these experiments, but while Mr. Guest fully recognized the necessity for using solid test pieces in some cases, he considered that in others tubes would give useful and reliable results. The whole problem of compound stresses in mild steel appeared to have closely approached solution. It was a fortunate circumstance that the problem had been attacked by the authors in totally different directions. He considered that the axis of stress was never coincident with the axis of the specimen, although in his own tests he had endeavored to make them coincide. The ordinary testing machine was merely a weighing machine, not an instrument of precision, and too much should not be expected from it. The chief point raised by Professor Smith was that where tubes were loaded in compression they might fail through secondary flexure. Mr. Mason had also had that kind of trouble, but, of course, when it occurred the tests must be rejected. Professor Smith had stated that engineers seemed to lack confidence in tests in tubes because they knew the probability of flaws existing in cheap tubes, and this naturally made them suspicious even of tests in good tubes.

Mr J. P. E. C. Stromeyer regretted that Mr. Mason had not given the hoop-tension, which would have completed the curve. With regard to Professor Smith's paper, the author seemed to infer that when a ratio of maximum stress to mean stress did not exceed a certain amount the material would not fail. From this it might appear that the stress could be increased to infinity without failure, if only the ratio were not exceeded. [Professor Smith rose and pointed out that stresses on the third plane had to be taken into consideration, and that the speaker's conclusion was erroneous.] With regard to the use of the sphingometer, he had arrived at the conclusion, as long as 20 years ago, that several instruments should be used to ascertain the elastic limit. He had always used two instruments, and for testing in connection with a Blackfriars' Bridge he used four One objection to Professor Smith's instrument was that the coiled metal strip was not of the same material as the metal which was being tested, and the difference in the coefficients of expansion would affect the accuracy of the instrument

The Physical Society.

The fifth annual exhibition of physical apparatus was held at the Imperial College of Science, South Kensington, on December 14. The exhibits fully maintained the standard of excellence of which the experience of previous years warranted the expectation

The Bausch and Lomb Optical Company had some very efficient microscopes of new model, microtomes, electrical centrifuges and their opaque projection apparatus. The Cambridge Scientific Instrument Company showed new patterns of the Féry radiation pyrometer, in use with a Méker furnace, having decided advantages over last year's types; automatic temperature regulators, a newly designed Duddell thermo-galvanometer, and a very sensitive gas-leakage indicator. On the stand of Cassella & Company were Captain Sankey's metal-bending tester, recording rain gages, a gradient telemeter level, Hepworth's electric artificial horizon, and the Hennah & Rissel automatic safety-course recorder and indicator for ships. Harry W. Cox & Company exhibited large induction coils for radiography and wireless telegraphy, a new type of gas interrupter, and wireless telegraphy sets.

Mr. T. Thorne Baker's instruments for telegraphing photographs, shown in operation by the *Daily Mirror*, attracted considerable attention. Elliott Brothers displayed the Wimperis accelerometer and gradient measurer, for which are claimed accurate and rapid measurements of starting acceleration, retardation, comparative braking efficiency, tractive effort at varying speeds, and slopes and gradients. They also had an effective selection of their well-known electrical instruments. Everett, Edgcumbe & Company's exhibit consisted mainly of electrical measurement instruments and photometers. Gambrell Brothers showed some well-designed instruments, including their new "foolproof" pointer and reflecting galvanometer. Mr F. Harrison Glew demonstrated his novel "radium collector" for atmospheric electricity, which can be employed to give time records, operate continuous electric chimes and perform other like operations, also an electric recording inclined plane and spark counter, and an actinium emanation lamp. John J. Griffin & Sons exhibited Sand's apparatus for rapid electro-analysis of metals, a gamma-ray electroscope, and a temperature recorder connected to quartz-glass platinum resistance thermometers.

Notable among Mr. James J. Hicks' instruments were a compensated micro-manometer, indifferent to vibration or changes of level, and a meteorograph for attaching to kites to obtain a record of pressure, temperature, humidity and velocity of wind in the upper air. A. Hilger & Company had a capital display of spectroscopic apparatus, and a 56-plate diffraction grating. The Marconi Wireless Telegraph Company had their improved valve receiver in operation. Nalder Brothers & Company showed a Duddell's patent bifilar vibration galvanometer and Mansbridge's variable standard of self-induction; Nalder Brothers & Thompson, a telethermometer, consisting essentially of a moving-coil ohm-meter combined with a Wheatstone bridge, and a lamp-testing wattmeter. Negrette & Zambra showed meteorological instruments. Newton & Company made an attractive feature of gyroscopes, synchronous springs and pendulums, and the Wilberforce spring.

Mr. Robert W. Paul demonstrated the use of the Sumpner reflecting dynamometer and the Paul single-pivot dynamometer. The Reason Manufacturing Company showed Wright's electrolytic meter, two other forms of meters, and a very ingenious battery-driven clock of very simple and apparently efficient mechanism. Messrs. Ross., Ltd., exhibited excellent cameras and microscopes; Siemens Brothers & Company had an extensive assortment of electrical instruments, including a portable current transformer for accurate laboratory work. Snell & Tinsley had on their stand several instruments embodying new developments, among which were Drysdale's alternating-current potentiometer, the sine flux phase shifter, a phase-shifting transformer, and an improved siphon recorder. The Weston Company made an especial feature of their models 151 and 156 voltmeters and ammeters, for which they claim no inductance error, no discernible working error, no chamber error, dead-beat, and very uniform scale. The mineralogical and metallurgical microscopes shown by Carl Zeiss also deserve mention.

During the afternoon and evening Prof C. V. Boys, F.R.S., gave two demonstrations with soap bubbles, after which Prof S. P. Thompson, F.R.S., showed some combinations of mica and selenite crystals.

The Faraday Society.

The proceedings at the annual general meeting on Nov. 30 were very brief. Dr. Sands' paper on the electrolytic determination of lead as peroxide was read by Dr. F. Mollivo Perkin. The speaker, who opened the discussion, said he quite agreed with Dr. Sands as to the necessity for high density of the peroxide, the employment of high temperature, initial elimination of water by alcohol followed by ether, and drying at 200°. Dr. Seuter briefly pointed out some apparent discrepancies. Dr. Perkin replied that the difficulties which had arisen were due to omission of the working with alcohol and ether. He had not arrived at satisfactory results with alkaline solutions. There was very great difficulty in freeing the peroxide from alkali. With the nitric solution the whole of the lead was deposited in about 20 minutes, but with alkaline solutions a much longer time was required. The other papers evoked practically no discussion.

New Uses for Blast-Furnace Slag.

A new process for the utilization of blast-furnace slag has been worked out by W. P. Thompson Company, of Liverpool. Sand and sodium sulphate, with a little lime if required, are put into the furnace with the result that the slag is converted into a glass, which can be cast into blocks or rolled out, with or without wire reinforcement, into sheets for use as slates, slabs, tiles, building and paving blocks. Where the introduction of sand and sulphate into the blast furnace is not permissible, these materials are added and melted with the slag after this has been run into a reverberatory furnace; but this process demands care to ensure thorough mixing, and entails increased charges for fuel. The inventors claim that they can produce roofing slates of any size, shape or color at less than half the cost of Welsh slates, while this translucency is a great advantage. Building blocks of this material have a polished surface which will not permit adherence of sooty matter and thus always retain a bright appearance, and are, moreover, quite waterproof. The Patent Corporation, of Liverpool, is experimenting with slags from various sources.

LONDON, January, 1910.

Synopsis of Metallurgical and Chemical Literature

Iron and Steel.

Cementation by Carbon has been studied by L. GUILLET and CH. GRIFFITH, their results being published in *Revue de Métallurgie*, October last. Their object was to determine if carbon alone would cement iron by contact in a vacuum where the absence of gases was assured. Special precautions were taken to first remove dissolved gases from the iron and from the carbon used. The carbon was tested simply in contact with the iron and mechanically pressed against the iron. Their conclusions are important.

(a) In a vacuum, pure carbon does not cement iron unless mechanical means are provided to press it into contact with the metal. As the pressure is increased, cementation increases.

(b) Carbon *alone* plays but an insignificant part in industrial cementation processes.

(c) Dissolved gases, from iron or carbon, will promote cementation.

Moisture in Cupola Blast is discussed by Engineer A. MESSERSCHMIDT, of Wiesbaden, in *Stahl und Eisen*, Dec. 1. He calculates that since as much as 15 cu. m (525 cu. ft.) of air is blown in per kilogram of coke burned, that this may carry in wet weather as much as 0.2 kg of moisture, whose decomposition absorbs some 10 per cent of the calorific power of the coke. The damage done cannot be repaired by simply using 10 per cent more coke, because the real factor affected is the combustion temperature before the tuyères, and while this is materially lowered by the decomposition of moisture, it is not regained by increasing the coke. It is, therefore, common experience to find the cupola iron running cold in damp, warm weather, and unable to make sharp, thin castings. Messerschmidt cites a case where the cupola blast was taken from an underground conduit 15 m long, which was often partly full of water, thus giving air to the cupola saturated with moisture. Drying of the cupola blast will save melting coke, and give a more uniformly heated and hotter quality of melted iron.

Corrosion of Iron.—In the very interesting yearly report of the Bureau for Testing Materials of the Institute of Technology of Berlin for 1908-9 an account is given of the results obtained in the researches of E. HEYN and O. BAUER. The authors had formerly studied corrosion of iron in a solution of one special salt in water. They have now extended their investigation to the solution of salt mixtures. One special point is emphasized: In their former investigations the pieces of iron were completely suspended below the surface of the liquid. The speed of corrosion depends in this case on the quickness with which fresh oxygen can come by diffusion to the surface of the iron from the surface of the liquid. If, however, the iron samples are only partly suspended within the liquid, the rust which forms along the line of contact between the iron and the air acts as a transmitting medium for the oxygen downward. It acts like an oxygen sponge. The speed of rusting of the iron below the surface of the liquid depends now also on the nature of the rust; if this is porous or spongy it is a better transmitter of oxygen than if it is dense and compact.

Various cases of corrosion of boiler tubes and other apparatus were investigated. The general public usually blames the steel. But the bureau has repeatedly pointed out that in most cases the cause of strong corrosion is not to be found in the material of the steel, but in the method of operation. For instance, the way in which the feed water is supplied to the boiler may have considerable influence. If the water has an opportunity to absorb considerable quantities of oxygen by saturation with air, the oxygen is set free in form of little bubbles when the air is heated during operation. The oxygen bubbles adhere to the iron surface and produce corrosion. The bureau had formerly recommended the use of charcoal filters in the pipes for the feed water, but no results from practice have yet been reported. In five cases of corrosion of boiler tubes which were investigated the fact was established that the fault was not in the steel; in almost all cases the nature of the water was to be blamed, since very pure water (distilled water) was used. The bureau emphasizes strongly that the distilled water attacks iron in presence of oxygen far more strongly than most ordinary kinds of water. In one case the iron had been painted with a protected paint almost over the whole surface, with the exception of one end which had been left unpainted. This showed strong corrosion and it was found that the corrosion had also progressed from this end further below the protective film of paint.

Rail Steel.—In the same report a comparison of the microstructure of various kinds of steel is reported. Electrically refined rail steel was found free from slag enclosures; all other kinds of rail steel investigated were found to contain slag enclosures.

Ductile Electrolytic Iron.—At the last convention of the German Bunsen Society the Langbein-Pfanhauserwerke A. G. of Leipzig exhibited various samples of electrolytic iron made by the method of F. Fischer, from ordinary "commercial iron" with cathodic current densities up to 20 amperes per square decimeter or more (the composition of the electrolyte being not

stated. This electrolytic iron which has properties quite different from Burgess' electrolytic iron, contains not more than 0.05 per cent impurities (Gumlich gives the following analysis: 0.024 C, 0.004 Si, 0.008 Mn, 0.008 P, 0.001 S.) It is soft, the hardness in the Brinell scale is 92 unannealed, 62 annealed (while silver is 91, aluminium 52). Rolling increases the hardness; when a 3-mm plate was rolled out to 1.2-mm thickness, the hardness increased from 90 to 126; further rolling out to 0.6-mm thickness increased the hardness to 175. After annealing, however, the hardness dropped again at once to 60 or 62. This kind of electrolytic iron is easily worked, cut with the knife, rolled cold, and can be forged. It can be hardened in the whole or in parts by absorption of carbon. The magnetic qualities are excellent. Electrolytic iron sheets in thicknesses from 0.1 mm or less to 8 or 10 mm can be easily made by deposition on a metallic cathode. For steel cuts or electrotypes this electrolytic iron is specially suitable, since it is possible to carry out the process directly in such a way that the front of the cut is hardened, while the back is ductile. Seamless tubes, made by this process, were also exhibited (20 mm diameter, 1 mm thickness), also a lead pipe of 20 mm diameter and 0.5 m in length, armored with an adhesive iron coating of 1 mm thickness. (*Zeit. f. Elektrochemie*, Aug. 15, 1909.)

Electrolytic Steel.—A. Muller (*Métallurgie*, 1909, p. 145) has experimented largely on this subject. As anodes he used various soft steels and soft iron; as cathodes, iron, copper, lead, tin plate. The deposited iron detaches most easily from copper or lead. The best electrolyte was found to be a 30 per cent solution of double iron-ammonium sulphate, worked cold. The best cathodic current density was between 50 amp and 80 amp per square meter (5.5 amp to 7 amp per square foot). It is recommended to work under the following conditions: Use anodes as pure as possible, enclose the anodes in porous cells, replace the electrolyte daily, clean the anodes frequently by brushing in dilute HCl, keep the electrodes quiet and the electrolyte unagitated, protect the surface of the bath from the air by a layer of paraffine, keep the current below the higher limit named, use cathodes carefully cleaned and greased, use an electrolyte free from carbon. A sulphate electrolyte will always give iron deposit with a little sulphur—0.006 per cent when using perfectly pure anodes. The deposits contained also 0.012 to 0.014 per cent of hydrogen and 0.010 to 0.035 per cent of nitrogen. When such specimens were heated they showed numerous points of disengagement of heat, due to the reactions of hydrogen, but these disappeared on repeated heatings. The critical points showed distinctly at 894° and 761°. The fusion point was determined on a specimen containing 0.017 per cent C, 0.089 Si, 0.028 P, 0.025 Mn and 0.037 S, by heating in vacuum in a magnesia crucible, as between 1485° C. and 1525° C.

Recovery of Flue Dust.

Friction System.—Mr. Charles W. Goodale, of Butte, Mont., contributes an interesting note to the discussion of Mr. D. W. Bronton's address on modern progress in mining and metallurgy in the Western United States. It is printed in the January issue of the *Bulletin* of the American Institute of Mining Engineers. Mr Goodale describes the friction system designed for the recovery of flue dust from furnace gases as used at Great Falls. Screening tests on the blast furnace charges of smelting ore, and on the fine concentrate treated in the McDougall furnaces, show a high percentage of fine material, which would naturally be carried into the flues, and at a high velocity of the furnace gases through the flues a considerable loss in dust would inevitably occur.

Before deciding upon the friction system a flue was built 300 ft. long, 4.5 ft high and 4 ft wide, through which the furnace gases could be drawn in measured volume and temperature, and at varying velocities. Two tests were made maintaining a velocity of about 500 ft per minute, and with no obstructions or dust arresters in the flue. The amount of dust was determined per unit volume of gas; then similar determinations were made with baffle plates, Freudenberg plates (of sheet iron, suspended parallel with the direction of the flow of the gases), with numerous contractions and expansions, and with wires (patented by Roesing in the United States in 1890). It was found that the wires gave nearly as high an efficiency of dust recovery as the baffle plates, and with very much less frictional resistance to the passage of the gases. It was then decided to build a dust-chamber of such dimensions that the furnace gases would not have a velocity greater than 500 ft. per minute through it, and to fill this chamber with steel wires.

All the furnace gases from the several departments are assembled through individual flues in an up-take in the furnace building. From the top of this take-up a cross-take leads over the smelter buildings and tracks to the dust chamber. The cross-take is 34 ft. wide and 20 ft. high. The main dust chamber, rectangular in shape, is 367 ft. long, 176 wide, 21 ft. high. Steel-wire netting, 1⅝-in. mesh, is bolted to the I-beams of the roof, and at alternate intersections of the netting wires, steel dust arresting wires, No. 10 gage, weighing about 1 lb. each and reaching nearly to the floor of the chamber, are hooked on. From the entrance to the chamber, and for a distance of about 150 ft., the space is fully occupied by wires; then comes a length of about 50 ft. with no wires, then 150 ft. filled with wires. In the vacant space, air ducts, both from the basement and the roof, are provided, so that the temperature from that point on can be reduced and the condensation of arsenic effected on the wires.

The purpose of this arrangement is to collect, as far as possible, the dust which is carried along mechanically by the furnace gases in the first part of the chamber, which leaves the condensable elements to be recovered in the upper part. Experience has shown that at or below the condensing temperature of arsenic the wires become heavily coated, and it is therefore necessary to shake them. Provision has been made for this. The dust chamber is divided longitudinally by a partition wall, and dampers placed at the lower and upper ends of the chamber make it possible to deflect all the gases through either half if it is so desired. Leading from the dust chamber to the chimney, which is 506 ft. high and 50 ft. in diameter at the top, is a flue 1200 ft. long, 48 ft. wide and 21 ft. high.

In the floor of the dust chamber there are more than 1000 sheet-steel hoppers, arranged in 22 lines, and a complete system of tracks enables the dust to be drawn from any hopper at any time. The cross-take is also provided with hoppers, and a hopper crane draws off the dust and conveys it to chutes leading down into the bottom of the up-take, where there are hoppers from which the material can be drawn into the charging cars for the reverberatory furnaces. There are 1,215,000 wires in the dust chamber, weighing about 608 tons, and nearly 3500 tons of structural steel in the flue system. Recording thermometers and pressure gages have been placed at the entrance and exit of the dust chamber and in the flue near the chimney, so that complete information regarding conditions is available.

Precious Metals.

Assay of Gold Alloys.—At the meeting of the Institute of Metals, Jan. 18, in London, Mr. Ernest A. Smith presented a paper on the assay of industrial gold alloys. In this paper Mr Smith gave a brief description of the methods in general use for the assay of industrial gold alloys, and embodied the results of experimental work carried out some years ago at the Royal School of Mines, and more recently in the Metallurgical Department of the University of Sheffield. The alloys dealt with are those of definite composition or "standard" alloys specially prepared for industrial purposes, and also those of more or less indefinite composition resulting from the treatment of scrap, lemel, sweep, and such substances obtained during the processes of manufacture.

After giving examples of the composition of some of the alloys in general use by goldsmiths and jewellers, which are

mainly ternary alloys of gold-silver-copper, Mr. Smith discusses the various methods of sampling and the precautions to be taken in the case of alloys in which segregation has taken place. Attention is drawn to the importance of removing the "colored" surface resulting from the "pickling" before taking the samples for assay. When this "colored" or enriched surface is included in the sample very serious errors may be introduced into the assay results in the case of sheet metal and wire.

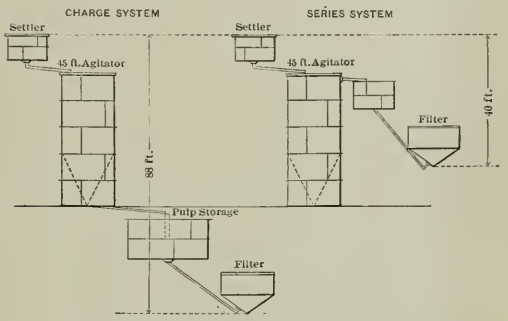
The question of the best proportion of lead to be used for the cupellation of gold alloys is then considered, attention being drawn to the fact that copper has a greater affinity for gold than for silver, consequently a larger proportion of lead is required to ensure its oxidation when combined with gold than when combined with silver. It is also pointed out that the separation of copper from gold is greatly facilitated by the presence of silver.

The quantities of lead used by different assayers experienced in assaying these alloys are given in a table. Brief reference is made to the methods in general use for charging the assays into the furnace, and the results of experiments on adding the lead in two separate charges (viz.: adding one-third after the other two-thirds have worked off).

The chief item of the paper is the comparison of the assay methods used for industrial alloys, based on experimental work, and it is shown that the results for the gold assay are invariably higher when determined by direct-cupellation with parting silver than when determined indirectly by double cupellation. The importance of using check assays in all cases where extreme accuracy is desirable is emphasized by Mr. Smith. The method of double cupellation, or "parting-assay," in which the gold and silver are determined in the same assay piece, is largely used by trade assayers for the valuation of lemel bars, and like substances, and in the hands of experienced assayers the results are sufficiently accurate for commercial purposes. In making assay by this method, it is well to remember that it is the weight of the gold which is the most important, because of its value, and the working conditions should be such that no undue loss of gold is occasioned. The different methods of reporting assay results are referred to. The decimal system is now very generally adopted for reporting gold assays, but the older "carat" system is still in use, as the generality of workers and dealers in gold and silver are more conversant with this system of computation than with the decimal equivalent. (From advance sheets.)

Cyaniding Slime.—In the January issue of the *Bulletin* of the American Institute of Mining Engineers, Mr. MARK R. LAMB discusses the two methods of treating pulp in air-agitation tanks. The usual method is to fill each tank in turn, agitate the mixture the required period and then discharge the treated pulp into a storage tank, from which it is drawn to the filter as required. A second and later method is to run the pulp from the tube-mill, classifier, thickener or settler into the first of a set of tanks, and thence continuously or in series through the remaining tanks, finally drawing off the pulp to a continuous filter, or to a pulp-storage tank if the filter is of the intermittent type. Mr. Lamb emphasizes the advantages of the latter method and mentions that in the design of a recent cyanide plant the estimated cost of agitation tanks, storage tanks and pumps was 30 per cent higher for the charge-agitation arrangement than for the series plan. An objection which might be raised against the series method is that some of the pulp might get through with little or no treatment. The author shows by simple approximate calculation that this is out of the question and that it is physically impossible for any particle of the pulp to go through the series of tanks in less than a certain minimum period. This minimum period gives the series method a big handicap, and one which increases directly with the number of tanks used. In fact, the resulting low circulation velocity makes the operation resemble the treatment of pulp in a horizontal tube of the same diameter as the agitation tanks and of a length equal to the combined lengths, having the agitation at right angles instead of parallel to its length.

Mr. Lamb mentions some interesting results obtained in tests on a small scale, with tanks of a capacity of 100 lb. of dry slime in a 2-to-1 pulp. With pulp containing coarse sand (and even with fine sand in a thin pulp) care must be exercised in drawing the pulp from one tank to the next in series, otherwise either the sand or the slime will accumulate. If the drawing-off pipe is merely flanged to the tank, the outflowing pulp will contain a greater proportion of slime to sand than is



CHARGE AND SERIES SYSTEMS OF CYANIDING SLIME.

contained in the average of the pulp, since during agitation by this method the sand has a tendency to sink through the pulp as soon as discharged through the central air-lift, rather than to work out to the sides of the tank with the flocculent slime. This difference in pulp flow is greater with a thin mixture and less with a thick one, and can be utilized practically in a very simple manner if it is desired to agitate the sand longer than the slime. A concentration of sand in the tank will be attained by drawing the slime from a quiet point in the circumference of the surface of the pulp. To do this, a discharge pipe, pivoted at the side of the tank, is arranged to swing in a horizontal plane and to be placed and held at any desired point in its arc between the central pipe and the side of the tank. After the desired initial concentration is attained, this discharge pipe is then placed so as to draw off a mixture of the same proportions of sand and slime as that being fed to the tank, which will maintain the charge in the tank at a higher ratio of sand to slime. Thus the slime will go through faster and the sand slower than the average pulp flow.

To illustrate this point, imagine a tank containing 100 tons (dry weight) of pulp consisting of 3 of sand to 1 of slime. Admit a stream of pulp carrying 100 tons in 24 hours, which consists of half sand and half slime, drawing off an exactly similar stream. The slime which was originally in the tank (25 tons) will be replaced twice in 24 hours, by the 50 incoming tons, while the original sand (75 tons) will be replaced in only two-thirds time. In other words, the slime will receive a 12-hour treatment and the sand will receive a 36-hour treatment. Mr. Lamb considers this one of the important advantages of the "series" system.

A point of great advantage possessed by the series method in the design of many plants is the saving in difference of level required in the site. The agitation tanks, if used in this manner, need not require more than from 2 to 4 ft. difference in level between the inlet and the outlet, depending to some extent upon the number and size of tanks and the distance apart, but also and mainly upon the margin of capacity required to provide for fluctuations in pulp feed and discharge. This margin depends largely upon the type of filter used. Ordinarily, the pulp will be

drawn from near the top of the last tank, while in the "charge" system the outlet is at the bottom of the tank. The accompanying figure shows this difference.

In the series system no storage tank is needed below the last agitator tank if a continuous filter, such as the Oliver or the Ridgway, is used; only a small tank of a capacity to supply pulp to equal displacement of a loaded basket of leaves if a Moore filter is used, and a slightly larger tank (sufficient to fill the filter box with the unloaded frames in place) with a Butters filter. On the other hand, in the charge system the storage tank, even with continuous filters, must have at least a capacity equal to that of an agitator, and with either the Moore or the Butters filter must have a slightly greater capacity.

Continuous Collection of Sand for Cyaniding.—With respect to Mr. W. A. Caldecott's paper, abstracted in our January issue, page 42, Mr. C. O. Schmitt makes some eulogistic remarks in the *Journal* of the Chemical, Metallurgical and Mining Society of South Africa of November, 1909. He thinks that Caldecott's process represents a real advance in the treatment of sand. The satisfactory collecting of the sand contained in the final pulp leaving the battery, preparatory to treatment, is by no means a simple proposition. It is obviously necessary, in order to facilitate treatment, to collect the sand free from all slime, but this is not by any means always done, the slime contents of collected sand being sometimes as high as 10 per cent. Slime pulp should be treated in the plant provided for the purpose, and since the treatment of slime is, as a rule, less expensive than the treatment of sand, any slime retained in the collected sand not only costs more to treat than it otherwise would, but it also displaces sand which could be handled in its place, quite apart from the fact that the presence of slime in the sand-collecting vats interferes with the treatment. Mr. Schmitt emphasizes the excellent results obtained on the Simmer and Jack plant, using a 15-ft. table, although it is only of an experimental nature. The objection might have been raised to the introduction of further machinery into the already complicated reduction plant, but Mr. Caldecott has disposed of any such objections by pointing out that the continuous running of the filter table presented no difficulties; so much so that the arrangements made for temporarily reverting to the old style of working, in case of temporary failure, have not so far been needed.

The four chief advantages of the Caldecott process are summarized as follows: The sand collected is cleaner and contains less slime than is the case in the ordinary plant. The capital cost of the sand plant has been reduced by nearly 40 per cent. The space occupied by a sand plant has been reduced. The time of treatment is reduced to about two-thirds of that now occupied. The question of capital expenditure will appeal to most, and since the saving of 40 per cent on the sand plants amounts to about 10 per cent on the whole reduction plant the result accomplished is worthy of considerable praise. The saving on capital account may be still further increased by providing only one set of treatment vats, and while this may not be acceptable for very high-grade propositions there will be many instances where it could be justified.

The tendency all over the world is toward all sliming, and in view of the ease with which the average slime is treated, this is, in many cases, quite justified. "In view of the result obtained it is obvious that Mr Caldecott has done quite a good deal toward the desired end, and (in the writer's opinion) more than those who propose to spend a shilling in crushing and grinding, to save sixpence in the cost of the succeeding treatment. We are not by any means at a stage where the sand plant can be discarded," and in this connection the writer refers to an all sliming plant erected by Mr Charles Butters in Mexico which in spite of being intended as an all sliming plant contains a sand plant. The reason is that upon work having been started, it was found that the product from the crushing and grinding plant did contain what is usually termed sand and which did not yield sufficient of its precious metal contents.

Copper.

Cartridge Brass is the subject of a very interesting study by Capt. Grard, published in the *Revue de Métallurgie*, October, 1909. As is probably generally known, this brass must sustain great mechanical strains in being stamped or drawn into shape, and only the best copper and the very finest zinc can be used in it. It is usually made with 33 per cent zinc. Exhaustive mechanical tests were made with the brass as cast, worked, partially annealed and annealed, while an extensive microscopic study was simultaneously made. It was determined that from 0° C. to 250° C. this brass possesses its minimum of malleability; when worked, the structure showed broken octahedral crystals. Heated to from 250° to 400°, the normal properties commence to appear. Between 400° and 700° is a range for semi-annealing; heated between these limits the tensile strength diminishes gradually, but the elongation before rupture increases. Complete annealing is attained by heating to between 750° and 830°, but the upper limit must be approached circumspectly; slight impurities in the metal and possible errors in determining the temperature both make it advisable to keep below 800°. Annealing above this temperature causes a rapid falling off in the quality of the metal.

Failure of Brass Loco-Tubes.—At the meeting of the Institute of Metals, in London, Jan. 19, Mr. T. Vaughan Hughes presented a paper on the failure in practice of non-ferrous metals and alloys, with particular reference to brass loco-tubes. The paper describes an investigation into the cause of a breakdown of brass loco-tubes which led to serious casualties and Government inquiry. The breakdown occurred at the firebox end of the tubes nearest the firebox. The tubes were not corroded externally, but were thus affected internally, mostly along a semi-diameter. The corrosion appears to be the result of the action of volatile sulphur compounds from the fuel used (coke) in presence of hot reducing gases, which may have volatilized the zinc from the internal surfaces of the tube alloy. Condensed water vapor of an acid nature cleared the tubes during the morning stoking and at other times, allowing a repetition of above actions. Thus the tubes wore down internally until too weak to withstand the working pressure in the boiler. The action was by the author's further investigations found to be facilitated by the peculiar nature of the "scale," only 1/20 of a millimeter thick, which offered a resistance of 20 megohms to an e.m.f. of 250 volts when dry, and 150,000 ohms when wet.

This electrical measurement was taken as being indicative of the heat conductance of the "scale," and explains an overheating of the tube at the seat of breakdown and other parts. The "scale" consisted largely of silica, magnesia and ferric oxide, combined with a small amount of sulphuric acid initiated and held together by a soap of iron, aluminia and magnesia. The breakdown only occurred when the boilers were fed with untreated water supplied from a peaty source. Analysis of the "scale" and other data are briefly given. (From advance sheets.)

Aluminium.

Analysis of Aluminium and its Alloys.—A paper by Dr. R. Seligman and Mr. F. J. Willott was presented at the annual meeting of the Institute of Metals, in London, Jan. 18. The rapid development of the aluminium industry makes it desirable that everything appertaining to it should be standardized, among other things the methods of analyzing pure aluminium and its alloys. The technical methods described in this paper have been in use for a number of years, and it is hoped that they may form the basis for a future standard course of analysis. The aluminium of commerce contains from 0.15 to 0.6 of iron, 0.2 to 0.7 of silicon, and 0.02 to 0.06 of sodium, together with traces of carbon, oxygen and nitrogen, while occasionally small quantities of copper are found. The purity of the metal varies from about 98.5 up to more than 99.75 in exceptional cases. Owing to the impossibility of estimating the aluminium itself with sufficient accuracy, it is customary

to determine all the impurities and to calculate the purity of the metal from the figures so obtained. In most cases, only those impurities present in appreciable quantities are estimated, a course which has been fostered by the general ignorance of the influence of the minute quantities of the ingredients thus ignored on the properties of the metal. It is hoped that information will shortly be forthcoming as to the effect of these materials on the metal, so that the methods will have to be modified in this respect. A detailed description is given of methods of estimating silicon in its various forms, iron and sodium, together with figures indicating the accuracy of the various determinations.

The alloys of aluminium in common use contain, in addition to the impurities cited above, copper, zinc, nickel and magnesium, and as an additional impurity, lead. Alloys containing tin are met with in the form of solders or soldered joints. The methods which the authors use for determining these ingredients are described. Occasionally manganese, titanium and tungsten have to be dealt with, and the determination of these elements is briefly referred to, because the authors are of the opinion that the closer study to which these alloys are being submitted will enhance their importance and promote their wider introduction. (From advance sheets.)

Alloys.

Phosphor Bronze.—A paper by Messrs. O. F. HUDSON and E. F. LAW, on phosphor bronze, was presented at the meeting of the Institute of Metals, in London, Jan. 18.

The object of the authors' work is to indicate the relation between the mechanical and other properties of the copper-tin-phosphorus alloys and their constitution and structure. Copper and phosphorus combine with the formation of a definite phosphide of copper, which forms with copper a binary eutectic, and a ternary eutectic with copper and the compound Cu_4Sn. With less than 4.5 per cent of tin the slowly cooled alloys consist of copper holding in solution the tin and, perhaps, a small amount of phosphorus, and of copper phosphide in rather large but fairly uniformly distributed masses, there being no sign of the typical eutectic structure. With more than 4.5 per cent of tin the ternary eutectic, having the composition 81 per cent copper, 14.2 per cent tin, and 4.8 per cent phosphorus, and a melting point of 620° C., makes its appearance.

A diagram was given showing the constitution of all the alloys containing up to about 25 per cent of tin. For practical purposes the phosphor bronzes may be divided into two classes, (1) the malleable phosphor bronzes containing relatively small amounts of tin and phosphorus, not more than about 6 per cent of tin and 0.3 per cent of phosphorus, and (2) the cast phosphor bronzes containing in some cases as much as 12 per cent of tin and 1.5 per cent of phosphorus. The malleable phosphor bronzes consist of a homogeneous solid solution of tin and phosphorus in copper, or they may contain some phosphide of copper in the form of small rounded particles evenly distributed throughout the mass of the alloy. The cast alloys contain the ternary eutectic with some phosphide of copper. The ternary eutectic is exceedingly hard, while at the same time it possesses a good crushing strength, and it is to this constituent that the phosphor bronzes owe their property of resisting wear. The paper includes notes on the examination and analysis of the phosphor bronzes, and is illustrated by a number of photomicrographs illustrating the structure of the alloys. (From advance sheets.)

Copper-Arsenic Alloys.—A paper by Messrs. GUY D. BENGOUGH and B. P. HILL, on the properties and constitution of copper-arsenic alloys was presented before the Institute of Metals in London on Jan. 19. The paper is divided into two parts; the first deals with the mechanical properties of the alloys of industrial importance, the second with their chemical constitution.

In the first part the authors begin by stating the most important purposes for which these alloys are used, namely for locomotive parts and for dynamo brushes. They also give a statement of what are generally considered to be the peculiar characteristics of the alloys as compared with pure copper, namely, greater strength and rigidity, and greater resistance to the action of flames, i. e., of gases at high temperatures. The best proportion of arsenic to be used to insure maxima of the advantages named was shown to be a matter upon which opinions differ widely, and one of the principal objects of the paper was to bring forward data for an authoritative pronouncement on the matter. For this purpose five 1-in. round copper bars containing amounts of arsenic varying from 0.04 per cent to 1.9 per cent were prepared under ordinary industrial conditions by the Muntz Metal Company, and were thoroughly tested by the authors in three conditions, namely: (1) As rolled; (2) after being heated for various lengths of time in an oxidizing atmosphere; (3) after being heated for similar times in a reducing atmosphere. The reducing gases used in the third set of tests were coal gas, hydrogen and carbon monoxide. Since these gases are liable to come in contact with the copper-arsenic alloys used in practice in locomotive firebox construction, it was thought that an interesting light might be obtained on the causes of deterioration and failure of the alloys in practice.

Upwards of a hundred tensile tests were made to ascertain the exact conditions under which the mechanical properties of bars containing 0.04, 0.26, 0.75, 0.94, 1.94 per cent of arsenic respectively were spoiled by contact with gases at high temperatures. Briefly, these conditions were found to be: (a) Alloys containing between 0.04 and 1.0 per cent of arsenic were ruined by the action of reducing gases for three hours at 700° C.; in some cases a temperature as low as 600° C. was sufficient. (b) Similar alloys were not harmed by identical treatment in an oxidizing atmosphere, nor when the temperature was raised to 900° C. (c) Alloys containing 1.9 per cent of arsenic were not harmed by treatment in either an oxidizing or a reducing atmosphere.

With regard to the best percentage of arsenic to use in these alloys, the authors found that the alloying metal when present in quantities less than 2 per cent tends to increase slightly the tensile strength and the elongation of their alloys. They also consider that the homogeneity and the resistance to the action of reducing gases increase with increased percentage of arsenic up to 2 per cent.

The authors describe a series of experiments carried out to elucidate the *modus operandi* of the reducing gases in spoiling the alloys, and put forward tentative suggestions as to the means which might be taken to produce bars which would resist the action of reducing gases.

In the second part of the paper the authors describe the work undertaken to elucidate the constitution of these alloys, and give a diagram illustrating it under certain defined conditions. They confirm the existence of the compounds Cu_3As, and Cu_3As_2, already proposed by Friedrich, and deny the existence of the compound Cu_2As, proposed by Hiorns. (From advance sheets.)

Electrochemistry.

Fixation of Atmospheric Nitrogen.—In *Zeit. f. Elektrochemie*, Jan. 1, a review is given by F. HABER and A. KOENIG of the present status of fixation of atmospheric nitrogen. The following table sums up the results obtained with the three successful processes in commercial operation; the process of the Badische Company (Dr. Schönherr) (see our vol. VII, p. 245), the process of Birkeland and Eyde (see our vol. IV, p. 126 and VII, p. 304) and the process of Salpetersäure-Industrie Company (Pauling) (see our vol. VII, p. 430). The table gives both the yield in grams HNO_3 per kilowatt hour and the con-

	Grams HNO_3 per kw-hour.	Concentration in per cents NO.
Badische Company	75	2.5
Birkeland and Eyde	70	2
Pauling	60	1 to 1.5

centration in per cents of NO, since both items are of fundamental commercial importance.

The comparison with theoretical figures is difficult. The commercial yield of the process of the Badische Company is about 63 per cent of the theoretical value obtainable (without regeneration of heat) on the hypothesis that the oxidation of the nitrogen is a purely thermal process and that the temperature of the arc is 3800 deg. C. The authors give a very useful review of the various scientific investigations made in recent years on the mechanism of the oxidation of atmospheric nitrogen by electric discharges through air.

Calcium Carbide and Acetylene Tetrachloride.—A report by J. H. Vogel on the present situation of the calcium carbide industry in Europe is given in abstract in *La Revue Électrique*, Nov. 15, 1909. While in the past the consumption of calcium carbide in Germany has increased from year to year (30,340 tons in 1906, 34,916 in 1907, 39,180 in 1908), there is a decrease to 38,000 tons in 1909, due to the introduction of electric instead of acetylene lighting on the cars of the Prussian railways. With this single exception the consumption of carbide has further increased. During the past year dissolved acetylene (see our Vol. I, page 274) has been introduced in Germany. The manufacture of acetylene tetrachloride is now carried out on a large scale by the simple addition of chlorine to acetylene, without using any further compounds. It contains about 85 per cent of chlorine and 15 per cent of acetylene, and its manufacture is advisable where cheap chlorine is available. Since 1 kg of commercial carbide yields 1/3 kg of acetylene (285 liters) there are needed 85 kg of chlorine for 45 kg of carbide to produce acetylene tetrachloride. This is an excellent solvent and is used as a substitute for benzine and like materials, its great advantage being its non-inflammability. It is also made in Jaice (Bosnia) and in Runcon (England); at the latter place a plant capable of producing 1000 cu. m of acetylene per day has been erected. At both places, the process of the Consortium f. elektrochem. Ind. is employed. Another process has been worked on an experimental scale in Neustassfurt and is about to be started on a large scale. A derivation of acetylene tetrachloride is trichlorethylene, C_2HCl_3, which is a substitute for carbon tetrachloride. The latter has the disadvantage that it attacks iron at elevated temperatures. Trichlorethylene is made in Jaice in Bosnia and sold in carloads. The long experiments on the utilization of acetylene for the manufacture of lamp black appear to have been successful; in a plant at Friedrichshafen 1000 tons of carbide will be treated per year. This plant has a contract with the Zeppelin Company for the supply of large quantities of hydrogen for airships.

Bleaching Liquor by Electrolysis with Magnesium Cathodes.—The direct production of hypochlorite or bleaching liquor by electrolysis of alkali chlorides, depends on a good mixing of the anodic and cathodic products of electrolysis. The efficiency of this process is reduced by the production of chlorate and anodic oxygen and by the reduction of hypochlorite at the cathode. To prevent the latter the only remedy is to keep the ClO ions away from the cathode. By a well-known process of Imhoff and Müller this is accomplished by an addition of chromate to the electrolyte; this has such an effect that a very thin yet effective diaphragm forms automatically at the cathode surface thus preventing the ClO ions from making contact with the cathode. Betts and Sherry have proposed the use of magnesium cathodes. In the October, November and December issues of 1909 of *Elektrochemische Zeitschrift* M. F. Schmidt gives an account of an investigation in which he studied the reason for the good effect of the magnesium cathode. It is again the automatic formation of a very thin diaphragm right on the cathode. As soon as the magnesium plates are inserted in the solution they are covered with a film of magnesium hydroxide which prevents the ClO ions from making contact with the cathode. From a commercial point of view it is to be considered that on account of this film the internal resistance of the cell is increased. With a current of 1.6 amp. in the author's experiments, the voltage was 1.1 volt higher with the magnesium cathode than with one of platinum. Further the formation of chlorate increases with increasing concentration of ClO. With respect to the efficiency, the use of a magnesium cathode differs from that of a platinum cathode of the same size in so far as the same or a somewhat higher yield of active chlorine may be obtained with magnesium by more watts in a shorter time. But by increasing the magnesium cathode it is possible to decrease the voltage (and therefore the power) and nevertheless obtain a high efficiency.

Ozone.—According to a note taken from *Revue d'Électrochemie et d'Électrométallurgie* and printed in the London *Electrical Engineering* of Dec. 30, ozone prepared by electric discharges through air is sometimes found to contain oxides of nitrogen, and Boujeau has noticed the action of these oxides upon the lead pipes which conducted the ozonized air in water purification works. As a result, nitrate of lead has been found to contaminate the water, which is naturally a serious matter. For this reason it is recommended never to employ metallic pipes for conveying the ozone from the ozonizers to the sterilizing plant. As an indication of further progress made in the industrial sterilization of water by ozone, it is stated that at the town of Chartres, in France, drinking water is now obtained by purifying, with ozone, water from the Eure River. This contains originally from 3000 to 16,000 bacteria per cubic centimeter, but treatment with 2 grams of ozone per cubic meter of water renders it practically sterile. The installation, employing the Otto system, is a double one, each part being capable of sterilizing 6000 cu. m (212,000 cu. ft.) of water in 24 hours. A 40-hp steam engine raises the water a height of 11 m (36 ft.) and drives a 500-period 250-volt alternator. The voltage is then raised by a transformer to 20,000. The ozonizers have glass plates as dielectrics, with tin foil between them, and the air is passed between the plates; 50 watt-hours are required to produce 2 grams of ozone, and as this is sufficient to sterilize 1 cu. m of water, 12 kw are required for the 6000 cu. m in 24 hours. A project is stated to be on foot to sterilize Paris water in a similar manner, when it is hoped it will be possible to set up a plant which will be capable of sterilizing 1 cu. m of water with an energy consumption of 10 watt-hours.

Electric Vacuum Furnace Installation.—In our vol. IV, p. 223 (see also vol. VII, p. 427), an electric vacuum furnace of Arsem for experimental work was described with a vertical graphite helix as heater, in the center of which is the crucible. The "radiation screen" (a device for diminishing the loss of heat by direct radiation from the heater) is an annular graphite box, filled with graphite powder which is a poor conductor. In the January issue of the *Journ. of Ind. & Eng. Chemistry* of the American Chemical Society Mr. W. C. Arsem describes some modifications of this design. A larger size of the vertical type differs only in size and in details from the above. In the horizontal tube furnace the heater is a graphite tube, held in graphite clamps with a tight sliding fit, to permit expansion and contraction. Finally in the "box type" of tube furnace the chamber is a rectangular gun-metal box with a removable cover. The heater is made up of four graphite grids, connected in series. These grids are made by sawing slots in graphite slabs 5 in. x 18 in. x 3/4 in. The heated space enclosed by the grids is large enough to take a box-shaped crucible 4 in. wide, 12 in. long and 8 in. high, or 384 cu. in. The radiation screen is made up of eight box-like sections, each hollow and filled with graphite powder, the top section being removable. The research laboratory of the General Electric Company has two installations of vacuum furnaces each containing four furnaces with the necessary transformers, pumps, etc. A very convenient installation for small scale experimental work would consist of a small vertical-type tube furnace, a 10-kw flux-shunt transformer, a Geryk pump and a 15-kw wattmeter.

Electric Furnace Temperature Regulation.—A contrivance to maintain a regular temperature in an experimental electric

Physique by Mr. L. Kolowrat (also in London *Electrician*, December 31, 1909). In Fig. 1 is a resistance furnace fed by current from the mains *A*.

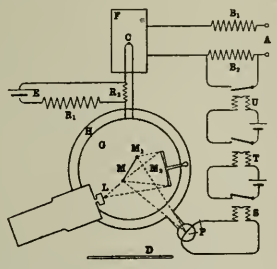


FIG. 1, APPARATUS FOR TEMPERATURE REGULATION.

The thermo-couple *C* is connected to a Le Chatelier galvanometer *G*, which carries on its movable part, in addition to the concave mirror *M* indicating on the scale *D*, a thin, flat glass mirror, 4x5 cm. in size. *L* is the filament of a Nernst lamp placed vertically, M_2 a spherical mirror with a gilt outer surface, and *P* is a Rubens thermoelectric cell, consisting of 12 copper-constantan elements. The position of the mirrors is so arranged that, when the temperature of the furnace reaches a determined point and the arrow of the galvanometer consequently registers at a certain angle, the rays of the lamp are focused on the junctions of the thermo-electric cell *P*. The current generated in the cell acts on a system of three relays, *S*, *T*, and *M*, which operate successively. By this means a resistance is introduced into the circuit *A*, and the heat of the furnace is consequently diminished. When this happens the deflection of the galvanometer decreases, the concentration of rays is removed from the cell *P* and the relay system shunts B_2.

The range within which the temperature of the furnace may be confined may be decreased by increasing the sensitiveness of the galvanometer.

Randall in the *Physical Review* (Vol. XLV, page 142) has described a furnace, the regulation of which can be accomplished by means of a thermo-couple attached to a galvanometer. This latter acts as a relay, but the principle involved is quite different from that of the apparatus just described.

Chemical Engineering.

Concentration of Sulphuric Acid.—In the *Chemiker Zeitung* of Jan. 11, Dr. G. LÜTTGEN remarks that the hopes which have been placed in the contact process for making sulphuric acid have not been completely fulfilled in the course of the last years. It had been wrongly supposed that the lead chamber process was doomed. The numerous difficulties of the contact process have not yet been overcome. The process is still very sensitive. On the other hand, various improvements have been made in concentration apparatus for chamber acid. These apparatus not only serve for increasing the concentration of the chamber acid (in some cases up to 98 per cent H_2SO_4), but they also permit the regeneration of the weak acids formed in some processes.

The first system discussed makes use of two series of 20 porcelain pans, arranged stepwise. The acid passes from one pan into the next. At the lower end a coke fire is provided by which the pans are heated. This system had the disadvantage that the porcelain pans were very liable to break. It has been improved by the use of pans of acid-proof metal or fused quartz; the loss by breakage has been reduced, but it still exists. The disadvantage of these pans is that they permit acid to trickle through, since after a certain time microscopically small cracks are formed. During the course of the last few years a coke filter has been added to this system. The acid obtained by this treatment is clear and may be easily concentrated to 92 or 93 per cent H_2SO_4. The consumption of coke is fairly high, about 150 kg (330 lb.) per ton of 92-93 per cent H_2SO_4. To pass the acid vapors into the coke filter, a small ventilator is used; the power required is small, amounting to ¼ hp for one hour and one ton of concentrated acid.

In the second system described a tower is used into which hot gases enter at the bottom, while at the top the chamber acid (52 to 53 deg. Baumé) is introduced in the form of a spray. Under the effect of the heat the acid mist is concentrated and the acid passes out of the tower at a concentration of 92 to 93 per cent. The steam mixed with acid escapes at the top. The ("volvic" stone) tower may have a height of 7 to 15 meters (23 to 49 ft.). The acid is injected in the form of a spray by means of a lead injector with a circular end-piece of cast iron with a nozzle in the center. This nozzle must be adjusted to the desired degree of concentration of the acid. It is therefore always necessary to change the nozzle whenever the degree of concentration of the acid is to be changed. There are therefore different nozzles used for 78 to 80 per cent, for 92 to 93 per cent and for 96 to 97 per cent acid. The inside of this injector contains a part in the form of a spiral which ends at the front in a point, and at the back in a cylinder. When the chamber acid is forced through this spiral passage, it assumes a rotating motion and leaves the nozzle in form of a rotating mist which fills the whole inside of the tower.

The weak point of the method is that a very pure acid is required which is taken from the second chamber and must be filtered very carefully, since any small impurity would clog the spray nozzle, or, at least, clog it partially. In the latter case the acid is not set into rotary motion, but is thrown in a straight thin stream against the tower walls. The acid becomes turbid and colored. In such a case the apparatus must be stopped and the spray nozzle must be cleaned. But this takes some time, since the attendant will not become aware at once of what has happened and a large quantity of dark acid may have formed meanwhile.

To remedy this the chamber acid is passed through a large sand filter, but this is not always successful. For the condensation of the acid vapors two filters are connected to the apparatus. Both may be filled with coke, but the second is generally filled with quartz. Between the tower and the first coke filter there is inserted a nine-meter lead column to cool the acid vapors and condense them partially. The movement of the gases is obtained by a ventilator at the end of the apparatus. The temperature in the upper part of the tower is 120 deg. to 140 deg. C., while the temperature in the upper part of the lead column is 90 deg. to 100 deg. C. This apparatus with its latest improvements requires 110 to 120 kg of coke per ton of 92-93 per cent commercial acid. The power required for operation is 0.75 hp per hour per ton of concentrated acid. The output of a plant of usual size is 10,000 kg of 92-93 per cent acid in 24 hours. The quantity of acid from the coke filter is also quite considerable. In 24 hours about 2000 kg of acid at 10 deg. Baumé and 500 kg of acid at 14 deg. Baumé are obtained. The price of such a plant when completed is 40,000 to 50,000 marks ($10,000 to $12,500). Since there are only a few plants of this kind in use and these have been in operation only a short time it is too early to give exact figures regarding the cost of maintenance, but the author thinks the repairs will be somewhat expensive. The third system discussed by the author (an improvement of the old Kessler system) will be dealt with in our next issue.

Pyrometry.—In the work on pyrometry, carried out by the Reichsanstalt in 1908, as noticed in London *Engineering* of Dec. 17, 788 thermo-couples were tested; 691 of these were of the Le Chatelier platinum, platinum-rhodium type. The electromotive force of these couples decreases when the couples are exposed to very high temperatures for many hours, and the whole length of wires for a new couple was therefore wound on a magnesia tube, without allowing the two wires to come into contact, and heated to 1400° C. in an electric furnace. Carbon, silicon and iridium, which had been held responsible for the change, were absent in these experiments.

It would appear that some of the rhodium evaporates and settles on the platinum wire, causing a change in the electromotive force, which, at the end of four hours, was equivalent to 35° C. This confirms an observation made by W. P. White in 1906, who found rhodium in the originally pure platinum wire. The effect is local and confined to those portions which are exposed to the highest temperature; that would explain the dependence of the electromotive force upon the depth to which the couple is inserted. The number of constantan-silver couples tested by the Reichsanstalt has diminished and there is a prejudice against their constancy. Repeated tests, during which such couples were heated for 12 days, finally to 600° and 650° C., did not bring out any discrepancy; the indications remained constant within 1 deg. The want of constancy may be due to the arrangements used in engineering practice. The standardization of the Wanner optical pyrometer (35 of these were tested) against black bodies by means of the Koenig and Lummer-Brodhun pyrometer is difficult, on account of the temperature determination in the black body by the aid of thermocouples. In the work on Seger cones, iridium, iridium-ruthenium couples and a tubular iridium furnace are used. Twenty cone temperatures have now been fixed; cone No. 20 has a softening point of 1530° C. But the research had to be interrupted because the iridium tube had to be repaired again.

Alcohol From Sawdust.—Concerning the manufacture of alcohol from sawdust in a plant at St. Marcel, Department of Ardeche, in Southern France, a recent consular report of Frank H. Mason, of Paris, states that this is a new, up-to-date concern and employs a process which consists in exposing sawdust to sulphurous acid gas, whereby the alcohol is generated and extracted without being mixed with or contaminated by the sulphur, as had always happened when sawdust was macerated in a solution of sulphuric acid under the older processes. Consequently it is claimed that alcohol made by the new process can be taken internally or used for any other purpose to which pure alcohol is usually applied.

One metric ton (2204 pounds) of sawdust yields by this process 100 liters (27.47 gallons) of alcohol, 20 kilograms (44 pounds) of acetic acid, and the residue or spent sawdust is pressed into briquettes and used as fuel.

Recent Metallurgical and Chemical Patents

Non-Corrosive Dead-Soft Open-Hearth Steel.—It has been known that in the last years the American Rolling Mill Company, of Middletown, Ohio, has developed a process for making in the open hearth a very pure steel which they have placed on the market under the name of "American ingot iron" and for which the important claim is made that it resists corrosion successfully. Exact information on the process is now available from two patents recently granted to Mr. Robert B. Carnahan, Jr., the superintendent of the American Rolling Mill Company. The company is working under license from the International Metal Products Company, of Newark, N. J., to which both patents are assigned. One (940,785) is a product patent, the only claim referring to "improved rolling mill and bloomery ingots characterized by a deoxidized and degasified slagless body crystalline in structure and containing at least 99.80 per cent of iron, and containing not over 0.14 per cent of sulphur, phosphorus, carbon, manganese, and silicon taken in the aggregate, and containing not over 0.05 per cent of oxygen." The other patent (940,784) refers to the process of making this steel. A basic-open hearth furnace is charged with pig iron or cast iron or molten iron. In practice there has been substituted low-carbon iron or steel scrap to a considerable extent, in some cases as high as 80 per cent of the charge. Lime or limestone is charged to reduce sulphur and phosphorus, these agents being preferably charged prior to charging the metal. The charge is then refined, as in making soft steel, by the employment of ore or agitation, or both, but recarburization at this stage is not necessary in case the charge melts specially low in carbon. Carbon, manganese, sulphur, and phosphorus are thereby reduced. This refining operation is carried out for a much longer time, from one to four hours more, than is usually employed in making high-grade soft steel; naturally, while the carbon is being more and more reduced, the melting point of the iron bath rises and the temperature must be gradually raised, until it is finally at least 2850° Fahr. The refining operation is considered finished when by bath test the bath will contain not over 0.14 per cent of sulphur, phosphorus, carbon, manganese and silicon taken in the aggregate. For the best results it is desirable and practicable to reduce this aggregate to less than one-half the percentage named, and to have neither carbon nor manganese over 0.02 per cent.

The refined metal is poured into molds while still at high temperatures, and while still molten it is deoxidized and degasified to such extent that the resulting product will contain not over 0.05 per cent of oxygen as determined by the method of Ledebur, and preferably considerably below this, and will contain at least 99.80 per cent of iron. "The deoxidation and degasification may be very satisfactorily accomplished by the addition of aluminium in the molten metal, say, 2½ lb. per ton. If done in the furnace it is recommended that aluminium pig iron may be used." Aluminium may be economized by partially deoxidizing the bath by employing pig iron, say, 2 to 8 per cent of the charge. The degasifying and deoxidizing agents must, of course, not be such as to lessen the above-mentioned purity of the ultimate product. In tapping the metal the slag is floated off and the product is thus freed from it. We comment upon this very interesting process on our editorial pages. (940,784 and 940,785, Nov. 23, 1909.)

Annealing and Hardening Furnace.—Mr. W. S. Rockwell patents a furnace for annealing and hardening small pieces of steel, copper, brass, etc. Since the furnace has already been described in this journal, it should suffice to say that it is an internally fired cylindrical furnace, with a spiral lining, the furnace being rotated at a certain speed and charged and discharged automatically, a pyrometer indicating the actual temperature at the point of discharge. The only manual part of the operation is that of firing, but as the fuel is constant, and the temperature is indicated by the pyrometer, it is only necessary to get the speed of the furnace and the temperature correct before starting, after which the entire operation is automatic. The patent is assigned to the W. S. Rockwell Company (940,280, Nov. 16, 1909.)

Mineral Wool.—In making mineral wool the molten slag or scoria as it comes from a cupola is blown by an air or steam blast into a blow tube and from there into a settling chamber. The commingling of the smoke and the hot filamentous slag acts to elongate and toughen the fibers of the mineral wool and completely convert the slag into filaments. In order to render the mineral wool waterproof and specially suitable for insulating boards and blocks, Mr. T. B. Parkinson introduces a heavy crude hydrocarbon oil (crude petroleum) in small streams or drops into the hot slag, as it comes from the cupola and before it enters the blow tube. The oil vaporizes, "the residue or smoke of the vaporized hydrocarbon being thus brought into intimate contact with the exterior surfaces of the flying filaments of molten slag and thoroughly coating the same." (945,583, Jan. 4, 1910. Assigned to Union Fiber Company.)

Roasting Furnace.—A novel construction of the rabbling mechanism for reverberatory roasting furnaces is the subject of a patent of Mr. Benjamin Hall. If the rabbling mechan-

ism travels from one end of the furnace to the other it often carries with it adhering unroasted ore. To avoid this, the present inventor makes the rabbles swing as a pendulum across the furnace. In order to push the material forward, the rabble shoes are tapered; the thicker end is toward the feed end of the furnace, so that the rabble shoes present a surface gently sliding down toward the discharge end, thus feeding the material along. (945,522, Jan. 4, 1910.)

Hot Blast Stove.—Since Dr. WALTER O. AMSLER'S new hot blast stove of the three-pass central-combustion-chamber type was described and illustrated in our December issue, 1909 (Vol. VII, p. 542) reference to the patent covering this construction must suffice here. (945,360, Jan. 4, 1910.)

Copper.

Smelting Sulphur Ores.—Mr. RICHARD FLEMING, of the General Electric Company, proposes to smelt sulphur ores, like copper ores of the pyritic variety, in the electric furnace as follows. The process is also suitable for smelting galena. It is carried out in a totally enclosed electric furnace. When the copper pyrite ore, which usually contains also iron pyrite and to which some silicious material is added as flux, is in a fused state, steam and air are blown up through it. The steam decomposes the melted sulphides and drives out the sulphur at the same time oxidizing the iron to form iron oxide, which combines with the silica to form silicates of iron. The copper settles at the bottom of the furnace as matte. The sulphur is given off as hydrogen sulphide, but at the high temperature of the electric furnace this is broken up into sulphur and hydrogen. If air is blown through the ore together with the steam, a certain amount of sulphur dioxide is formed, which yields the following two reactions:

$$SO_2 + 2H_2 = S + 2H_2O$$
$$SO_2 + 2H_2S = 3S + 2H_2O.$$

Hence the vapor is essentially a mixture of sulphur vapor and steam, together with the vapors of arsenic or zinc, etc., if these are associated with the copper. The vapor is condensed in a separate condenser. When a sufficient amount of copper matte has accumulated in the furnace it may either be run off to another furnace to be finally purified, or it may be separately blown with either steam, or with steam and air, in the same furnace. It is finally drawn off as metallic copper containing a small amount of impurities. (945,926, Jan. 11, 1910.)

Zinc.

Electric Zinc Smelting and Zinc Condenser.—In our Vol. VII, page 468, a full illustrated description was given of the electric zinc process of E. E. CÔTE and P. R. PIERRON, in operation in Southern France. A recent patent of the two inventors refers especially to the zinc condenser. This is a vertical cylinder with a lining of refractory earth and of greater diameter at its upper end than at its lower end. This condenser is kept at the proper temperature for zinc condensation by a vertical heating rod, in the center of the condenser. It is heated by an auxiliary electric current. It is a thin-walled tube of finely ground, strongly pressed refractory earth, filled with fragments of powder of retort carbon. The temperature in the condenser is adjusted by varying the length of this column of carbon, or by varying the size and state of comminution of these particles of carbon or by adjusting the current which passes through this column. There is only a comparatively narrow space between this vertical central core and the slightly inclined inside walls of the condenser and within this space the zinc vapor (which enters at the top) is condensed and the liquid zinc is drawn off from the inclined bottom. (944,774, Dec. 28, 1909.)

Zinc Oxide.—In a patent for a method of preparing zinc oxide for reduction Mr. H. PAPE emphasizes the disadvantages of the very loose condition of ordinary zinc oxide for reduction. He proposes to treat the zinc oxide in a muffle or reverberatory furnace, in which it is exposed for some considerable time, say, two to three hours, to great heat, which may advantageously exceed 1000° C. By this treatment the loose zinc oxide is condensed or solidified in such a manner that it coagulates into solid lumps and pieces, and this solidification can be carried to such an extent that the weight of a given volume of zinc oxide which has been thus treated and then reduced to pieces 3 mm in size is about five times as great as the weight of an equal volume of crude oxide, which is removed from the settling chambers or dust flues. When the zinc oxide has been coagulated and solidified by heat in the manner described it is withdrawn from the muffle or reverberatory furnace and allowed to cool. It can then be transported in the same way as roasted blende and after the larger lumps have been broken up it can be used in the same manner as blende for forming the mixture for reduction to zinc. The instability of zinc oxide, which is prejudicial in the reduction process, is entirely obviated by this means, as is also the coagulation of the oxide in the muffle during the reduction process. (947,399, Jan. 25, 1910.)

Zinc-Calcium.—The production of zinc-calcium and other similar alloys by melting together the two materials involves considerable loss. Messrs. G. O. SEWARD and F. VON KÜGELGEN propose to produce such alloys by the electrolysis of a mixture of salts of the two metals. For instance, for the production of zinc-calcium a mixture of calcium chloride and zinc chloride is used. However, the tendency of the current is to separate first only the zinc. To prevent this the zinc chloride is employed in a relatively small quantity. An electrolyte of fused calcium chloride is used, with a carbon or graphite anode, and an iron cathode of such dimensions relatively to the current used that the calcium is obtained in a molten condition. A current density of about 60 amp per square inch is suitable. Upon commencing the electrolysis a small proportion (from 1 to 5 per cent) of zinc chloride is introduced, and from time to time so much zinc chloride is added as is necessary to keep the concentration of zinc in the electrolyte constant. Calcium chloride is also fed to replace that decomposed, but the electrolyte is always kept so that the proportion between the zinc and the calcium salt remains constant or approximately so. The proportion of the zinc in the resultant alloy may be varied by adjusting the concentration of the zinc in the electrolyte. In similar manner may be produced alloys of calcium and aluminjum, calcium and magnesium, barium and aluminium, barium and magnesium, etc. These alkali earth metal alloys are much more easily obtained than the alkali earth metals alone, for the reason that their melting points are lower and that there is not so much tendency for redissolution as with the alkali earth metals alone. (944,826, Dec. 28, 1909.)

Resistance Alloy—Mr. WILBUR B. DRIVER patents a resistance alloy of nickel and manganese in which the nickel predominates. Pure nickel has a comparatively low resistance, only about 12 microhms per cubic centimeter. A mixture of 95 per cent of nickel with 5 per cent of manganese gives a resistance of about 25 microhms per cubic centimeter, or twice that of pure nickel. Eighty per cent nickel with 20 per cent manganese gives a resistance of about 70 microhms; while 70 per cent nickel and 30 per cent manganese has a resistance of about 100 microhms. The melting point of these alloys is estimated to be in the neighborhood of 2500° Fahr. These alloys all have the advantage of not corroding readily on exposure to the air. They have the further advantage of electric stability, differing in this respect from alloys of copper and manganese alone. (943,066, Dec. 14, 1909.)

Calcium Carbide.

A number of patents have just been granted to Mr. HERMAN L. HARTENSTEIN, whose activity in the calcium carbide field has been repeatedly noticed in this journal.

Method of Manufacture.—The object of one of Mr. Hartenstein's patents is the use of anthracite coal screenings in the manufacture of carbide, while avoiding the disadvantages of excessive smoke generation in the furnace during reduction or the higher voltage required on account of the presence of particles of hard coal in the charge. The lime is taken from the calcining furnace while highly heated and is mixed with a

mixture of 80 or 90 per cent finely comminuted anthracite coal screening and 20 or 10 per cent of powdered coke (breeze) or charcoal. The result may be still further improved and facilitated by the addition to the carbonaceous constituent of from 3 to 20 per cent of bituminous coal rich in tarry compounds, say, about 5 per cent. It is this addition of coke and bituminous coal to the anthracite screenings which overcomes the above-mentioned difficulties. (946,511, Jan. 11, 1910.)

Attaining Uniform Composition.—To secure more uniform composition and quality, Mr. Hartenstein proposes to empty various charges of carbide as they are drawn from the furnaces into a large storage reservoir, allowing them to stand for some time before solidification in final form. During this storage period the different charges become thoroughly mixed merely by the dumping of each new charge, the heat being kept up by the constant accession of carbide direct from the furnaces at high temperature. This not only secures greater uniformity of composition, but allows for the perfect completion of all reactions. When a sufficient quantity of carbide has been collected part is drawn off. A certain amount, however, always remains in the reservoir The advantages claimed for the process over the mechanical admixture of the finished product is that the properties of all the granules are the same, thus obviating the possibility of troublesome secondary generations of gas. (946,510, Jan. 11, 1910.)

Carbide in Globular Form.—For use in acetylene generators of the "carbide feed" type, Mr. Hartenstein makes a carbide in globular form, by subdividing the solid carbide while still molten or plastic. This may be done, for instance, by a method analogous to that of making drop shot, the molten carbide being allowed to fall down a shaft under such thermal conditions that it preserves its fluidity sufficiently long to form spherical or rounded drops prior to solidification. Another method is to deposit molten carbide on a revolving table, from which it is thrown outward by centrifugal force in the form of globules. The globules are allowed to harden completely before packing. The main advantages of turning out the product in this form is that grinding is unnecessary and the fine dust, so troublesome on account of its excessive surface exposure to the atmosphere and its irregular generating qualities, is avoided. (946,433, Jan. 11, 1910.)

Carbide in Aggregated Mass.—In a process very similar to the above the globules are assembled after they have solidified enough to retain their shape, but before they have lost their surface viscosity. The particles thus become autogenously united to form an open-textured honeycombed mass. (946,497, Jan. 11, 1910.)

Utilization of Carbide Fines.—By incorporating finely powdered carbide as it comes from the crushing and sizing apparatus into the molten carbide coming from the furnace, Mr Hartenstein produces a magma which solidifies without the usual piping and segregation, giving a fine grained homogeneous carbide block or body of uniform quality throughout and yielding but a relatively small proportion of fines on comminution (946,432, Jan. 11, 1910.)

Electrode Holders.—Finally two patents of Mr. Hartenstein refer to mechanical details of carbon holders for use with electrodes in large furnaces. (946,434; 946,435, Jan. 11, 1910.)

Electrolysis of Common Salt.

Mercury-Cathode Diaphragm Cell.—The cell of Mr. J. J. Rink, of Copenhagen, Denmark, for the electrolytic production of caustic soda and chlorine from common salt is essentially a mercury cathode cell, but the principal feature is that the mercury cathode is vertical. It consists of a vertical conduit plate, the pure mercury being supplied through a pipe on the top, and flowing downward on both sides of this conduit plate in a thin film. Anodes are placed on both sides opposite to this conduit plate, so that while the mercury film passes downwards, it is changed into a sodium or potassium amalgam. To prevent the chlorine, which is set free at the anodes, from coming into contact with the mercury or amalgam, diaphragms are inserted between anodes and cathode. The amalgam flows off at the bottom into a washing chamber, where the caustic is formed, the pure mercury being pumped up again to the top of the cell. (947,741, Jan. 25, 1910.)

Chlorate.—For the production of caustic soda and chlorine (bleaching powder) from common salt, it is all important to keep the anodic and cathodic products of electrolysis separate from each other, so much so that in the patent of the preceding abstract two means to accomplish this were provided; a diaphragm and the mercury cathode which absorbs the sodium ions and removes them from the field of electrolytic action. Just the reverse is true, if a common salt solution is electrolyzed to produce chlorate, as the chlorate formation depends on the interaction between the anodic and cathodic products of electrolysis. Messrs. Harry H. Bates and Folger Adams, of Joliet, Ill., feed the salt solution to be electrolyzed into a central compartment which is entirely separated from the anodic and cathodic portion of the cell. The central compartment is entirely jacketed by the hot solution in contact with the electrodes so that the liquid in this central compartment becomes heated. From this central compartment the hot sodium chloride solution is let to the outer portion of the cell which contains the movable electrodes. By this motion the electrolyte is kept in violent agitation and the chloride is changed into chlorate. From this compartment the liquid is drawn off into the ordinary cooling or settling chambers. (944,650, Dec. 28, 1909.)

Electric Discharges Through Gases.

Hydrocyanic Acid.—The classical examples of producing gas reactions by means of electric discharges are the production of ozone and nitric acid from air. Ozone is produced by the silent discharge through air; the oxygen is the only constituent of the air which is thereby affected; about the mechanism of the reaction we know little; it has even been suggested that the reaction is simply due to the ultra-violet light which accompanies the silent discharge. The production of nitric acid from air by the electric arc, on the other hand, seems to be, to a large extent at least, a thermal phenomenon; that is, the nitric acid would be formed from air if the latter was heated to arc temperature by other means. An interesting example of the possible extension of such methods is the production of hydrocyanic acid from nitrogen and hydrogen. It is known that by passing a mixture of nitrogen and hydrogen through an electric arc produced between two carbon electrodes, combination of the gases with the carbon volatilized in the arc to form hydrocyanic acid takes place. In practice when it is attempted to carry on this process on a large scale, it is found that in order to obtain any large quantity of hydrocyanic acid it is necessary to pass the gases at a comparatively slow rate through the arc, since if they are passed rapidly through it, they do not become sufficiently highly heated. Professor O. Dieffenbach and Mr W. Moldenhauer, of Darmstadt, Germany, overcome this difficulty in an interestingly simple manner. The direct current arc is produced in a vertical furnace between a central carbon electrode at the top as cathode and a deep bed of unformed lumps of coke filling the lower part of the furnace as anode. In this way it is possible to produce a conical shape of arc playing between the carbon rod (which is only slowly consumed), and the lumps of coke below The mixture of nitrogen and hydrogen gases is led upwards from the bottom of the furnace through the incandescent bed of coke and is thus preheated, before it gets into the zone of the arc proper. (941,768, Nov. 30, 1909.)

Generation and Storage of Ozone.—When the storage of ozone is accomplished by compression after generation the heat generated by the compression results in dissociating part of the formed ozone back into oxygen. To prevent this, Mr. Frank Ashley, of New York City, compresses the untreated air or oxygen, withdraws the heat generated thereby, and then allows the pressure to quickly drop a few pounds in the ozonizing

chamber, thereby expanding the oxygen and cooling it, and then subjecting it to the action of the silent electric discharge while under pressure. The ozone is then stored in a suitable storage reservoir without permitting it to expand much below the pressure under which it is generated. (942,046, Dec. 7, 1909.)

Ferro-Alloys.

Electric Furnace Construction.—Mr. E. F. PRICE of the Union Carbide Company and the Electro Metallurgical Company has formally proposed an electric furnace for the production of ferro-alloys, in which a considerable body of the charge, for instance a mixture of silica, iron ore and carbon for the production of ferrosilicon, is maintained around depending carbons of opposite polarity, thereby embedding the zone of reduction, retaining the heat within the furnace, increasing the production of metal, keeping the slag in a liquid condition, and protecting the electrodes from the oxidizing and cooling effect of the atmosphere. While the use of this deep charge-body is advantageous, it is found necessary in practice to employ a charge of coarsely granular materials, in order to permit the ready escape of the large volumes of gas which are evolved during reduction. A finely divided charge, however, could be preferable in many respects, enabling reduction to proceed more rapidly and smoothly, but when a deep body of finely divided material is maintained around the electrodes, the gases escape violently by blowing out portions of the hot unreduced charge and agitating the molten or semi-molten contents so as to short-circuit the electrodes. To prevent this disadvantage Mr. Price withdraws the waste gases laterally in different directions beneath the surface of the finely-divided charge. For this purpose an inclined shelf is employed inside the furnace and surrounding the electrodes above their lower ends. It is made of cast steel and is water-cooled. The charge drops from above, rests on this shelf and surrounds the electrodes, and passes downwards in the space between the rims of the shelf and the electrodes. In this way part of the space just below the shelf is kept free of the charge. Through this space, the waste gases are withdrawn. (942,349, Dec. 7, 1909.)

Furnace Construction.—Mr. Price also patents another method by which the gases and dust arising from the operation are continuously withdrawn without interference with the operation of charging the furnace or with the accessibility of the electrodes for adjustment or renewal. In this construction the furnace consists of an open vessel; opposite series of vertically disposed electrodes depend into the same and a stack is disposed upon the bath and between the electrodes whereby the air-current flowing to the stack passes around and between the electrodes. (942,350, Dec. 7, 1909.)

Ferro-Tungsten Furnace.—In electric furnaces, for the production of high-grade ferro tungsten, containing over 70 per cent, usually but a limited quantity of ore is treated in a single furnace-run; after reduction it is cooled in the furnace and subsequently removed by chiseling it out. Mr. CHARLES E. WILSON, of Hood River, Ore., proposes to use a furnace chamber in the form of a crucible with removable sides of refractory material and provided with a graphite bottom which forms one of the electrodes. Extending downward through the open top of the furnace is the other electrode in the form of a graphite pencil. The ore is fed into the furnace around the pencil. The slag making constituents of the ore form the heat generating material. As the reduction progresses the ferro tungsten agglomerates between the electrodes and settles upon the carbon-crucible, and as a core of the alloy builds up the crucible is lowered so as to gradually build up a ferro tungsten core enveloped in slag. When it has attained sufficient height the current is shut off, the contents of the crucible are allowed to cool, the removable walls of the furnace are taken off and the slag is easily broken off the ferro-tungsten core. (943,290. Dec. 14, 1909.)

Powdered Metallic Tungsten.—A process for the production of powdered metallic tungsten has been patented by Mr. WILHELM MAJERT, of Berlin, Germany. Finely powdered anhydrous sodium paratungstate is incorporated with lamp black in the proportion by weight of 500 to 35. This mixture is then agitated and heated in a reducing atmosphere. Metallic tungsten and sodium tungstate are formed and the latter is washed out, first by the use of slightly alkaline water, then of water aciduated with HCl or H_2SO_4, and then with pure water, until a neutral reaction occurs. The metallic tungsten residue is then washed with methyl or ethyl alcohol and then with benzol or with the lightest benzine, portions of which are allowed to remain incorporated with the residue, producing a plastic mass which may be left in tightly closed receptacles until it is desirable to utilize it. This prevents oxidation of the powder. The process is said to be specially useful for the manufacture of tungsten filaments for incandescent lamps. The same process is applicable with any hexavalent high-fusing-point metal. Suitable salts for the process are sodium paratungstate (Na_2WO_4) and sodium paramolybdate ($Na_2Mo_2O_7$) from which one molecule of tungsten or molybdenum may be reduced, leaving in the residue the neutral salts of sodium, tungstate (Na_2WO_4) or sodium molybdate (Na_2MoO_4). (946,551, Jan. 18, 1910.)

Miscellaneous.

Cleaning Process.—A very simple process for cleaning metal articles, especially silver, gold, etc., is as follows: The silver articles to be cleaned are placed in a tin-lined vessel (or an aluminium dish), filled with a hot alkaline solution. On account of the different position of silver and tin in the potential series, this represents a short-circuited galvanic couple, current flowing from the tin into the solution and then to the silver and back to the tin. The oxide film on the silver is thereby reduced to metallic silver by cathodic reduction, and the silver is cleaned. It is an electrolytic process without the use of any current from an external source. But the action soon ceases, because the tin becomes coated with a film which is difficult to remove, and which prevents effective electrical contact with the silver article. To provide such contact Messrs. James D. Phillips and Carl Hambuechen provide for the introduction of an auxiliary metal electronegative to the anode. Thus, if the anode is zinc, and it is maintained in electrical contact with the metal electronegative to it such as tin, silver, or solder, the latter metal will remain bright and may thus be used to secure an interrupted contact with the article being cleaned. For instance, to clean silverware, a vessel of tin or enameled ware may be used with a corrugated sheet of zinc lying loosely in the bottom. The upper portion of the ridges or corrugations are tinned or soldered, this tin or solder constituting the auxiliary metal and remaining bright, while making contact with the silverware placed in the vessel. The tarnished silver thus gets automatically cleaned. A suitable solution is prepared by dissolving one tablespoonful of baking soda and one-half tablespoonful of common salt in one quart of water. (945,865 and 945,866, Jan. 11, 1910.)

Carbon-Silicon Dynamo Brushes.—Carbons, when impregnated with a certain amount of silicon, are very hard and excellent means for polishing a commutator. The higher the silicon content, the greater the hardness and the less the conductivity. A patent of G. Egly (assigned to Gebr. Siemens) recommends to combine the carbon and silicon with nitrogen. The molded mixture of carbon and silicon is heated in a nitrogen atmosphere in order to produce a compound of nitrogen silicon and carbon. In this manner a very uniform binding of the entire mass and great homogeneity of the body is obtained. The kind of compound which is formed by nitrogen combining with silicon may be very different; when a sufficient quantity of silicon is employed and when the mixture is sufficiently heated apparently the chemical compound C_2Si_2N is formed. (942,379, Dec. 7, 1909.)

A Comparison of Welding Methods for the Repair of Castings.

In *Stahl und Eisen*, of Dec. 29, 1909, Director E. Lamberton, of Merzweiler (Alsace, Germany), gives an interesting comparison of different welding methods for the repair of gray iron castings in foundries, repair shops, etc. As the article is based on experience from German practice, we give it here in translation almost in full, but have added some notes on American practice. The methods discussed below may, of course, also be employed for welding steel, but cast-iron repairs are chiefly considered in the following article.

In every works it becomes necessary at times to repair broken castings. In foundries it is also occasionally necessary to attend to certain surface defects, flaws, etc., of castings.

All the welding processes to be described depend on simply fusing the parts to be welded together, without introducing any other material into the joint. While the different processes are more or less simple, all require certain precautions.

In the first place, any welding operation produces internal stresses or tensions within the portions which are being welded on account of the great internal temperature differences. With an unelastic material like cast iron this is a serious matter, since there cannot be any equalization of the stresses between the hottest parts and the colder adjoining parts, which often results in a new break. This can be remedied to a certain extent by careful preheating, and cooling as described below.

While no detailed rules can be formulated comprising all cases in practice concerning the method of preheating the pieces to be welded, yet one general principle should be observed. The conditions under which the welded piece is cooled after welding should be the exact reverse of the conditions under which it is preheated before welding and should be identical with the conditions under which it was cooled after the original casting operation was completed. It is, therefore, important to preheat the pieces (before welding) slowly and continuously up to the maximum temperature which can be reached by the available means. The pieces to be welded together should be held in a firmly fixed position during the welding operation, and preferably in such a way that the joint to be made is in a horizontal plane.

Another important point which needs attention is to keep the two surfaces to be welded free from rust and any impurity. If there is rust on one of the surfaces, then the iron oxide is decomposed by the fused iron, the oxygen of the iron oxide combining with the carbon in the fused iron; gas formation results and the weld is porous.

If the repair relates to the removal of blowholes or flaws, the unsound portion of the casting must be completely cut out. This is illustrated in Fig. 1, where *A* is the casting, showing the unsound portion; *B* shows to what depth it is necessary to drill a cavity, which is then to be filled up with fused iron. It is also advisable to make the surfaces of the cavity not smooth, but rather rough or corrugated to make it easier for the fused iron which is added, to stick to and unite with the surface.

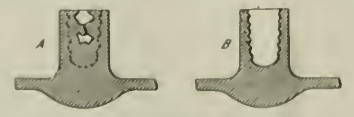

Fig. 1.—Removal of blowholes or flaws.

The above principles hold good in general whatever the special method of welding. They should be followed carefully in any case.

Mr. Lamberton's comparison refers to the following methods: The old welding process by simply adding fused iron (so-called burning on); electric welding; thermit welding; "autogenous" welding (oxy-acetylene or oxy-hydrogen welding). (It is true that in speaking of "autogenous welding" the oxy-acetylene or oxy-hydrogen process is now generally meant; but this is really incorrect. "Autogenous welding" means strictly joining or welding without use of a solder which would introduce a foreign material into the weld. Every one of the methods mentioned above is really an autogenous welding method.)

Burning On.—This old process consists simply in surrounding the casting to be repaired with a mold of sand. A large quantity of liquid metal is then run past the surface to be welded until it reaches fusion heat. The excess of metal runs

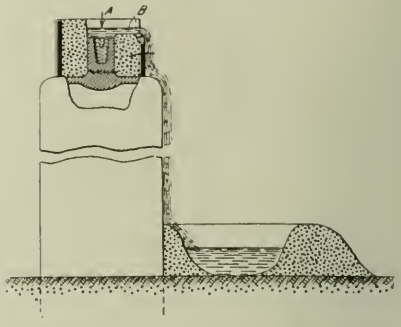

Fig. 2.—Repair of Fig. 1 by burning on.

off through an overflow channel which is preferably made of molding sand. Fig. 2 shows the repair of Fig. 1. The metal is poured at *A*. The outflow channel is at *B*.

Fig. 3 shows the repair of a machine frame, broken in operation. The arrangement of the mold is similar to the preceding case. The liquid metal is poured into *A*, and when it is seen to run off through *C* it is evident that fusion takes place at the desired depth; the channel *C* is then closed and further addition of fluid iron is stopped.

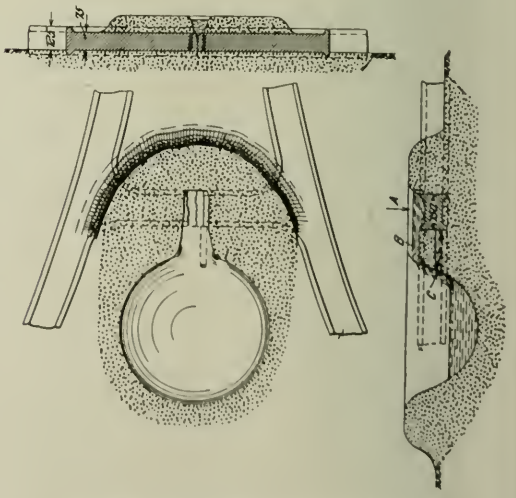

Fig. 3.—Repair of broken frame by burning on.

Fig. 4 shows the repair of a roll, to which a new boss is to be added. Some liquid iron is held for some time at *A* where the new journal piece is to be added, so that the contact surface is liquefied. The mold is completely filled with metal only after the weld has been produced in sufficient depth and after the overflow channel *B* has been closed.

With this process of welding by simple fusion it is important to arrange everything in such a way that the workingman who makes the repair can do it conveniently without being troubled by the heat of the iron running off through the overflow channel. The walls are covered with dry molding sand.

The molten iron which is added should have as high a temperature and fluidity as possible. The iron which is being added should come successively into contact with all points of the surface to be welded. This may be easily done with a

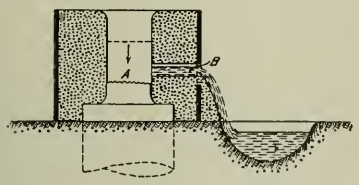

FIG. 4.—REPAIR OF ROLL BY BURNING ON.

hand ladle; but when large quantities of metal are needed and a crane must be used, it is difficult. It is necessary to make sure that fusion has been obtained at the desired depth; this may be done by inserting a perfectly clean and preheated iron rod.

After completion of the weld, the welded portion is covered with a layer of powdered charcoal and the whole is covered with dry sand to make sure that the cooling is slow.

The weld depends entirely on sufficient metal being run over the welding surface to bring it to fusion point. Then the flow is stopped and the metal retained in the mold will fuse with the casting. It is difficult to give general rules as to the quantity of liquid iron required; even to remove small surface defects 5 kg to 8 kg (11 lb. to 18 lb.) of metal are required to make success sure. For small repairs, like that of Fig. 3, 1 kg or 2 kg may be assumed per square centimeter (14 lb. to 28 lb. per square inch); for welding small axles or rolls 2 kg or 3 kg per square centimeter (28 lb. to 43 lb. per square inch). For large repairs these figures may be reduced one-half.

The above process can be used in any foundry, and is often employed with remarkable skill; but it must be remembered that

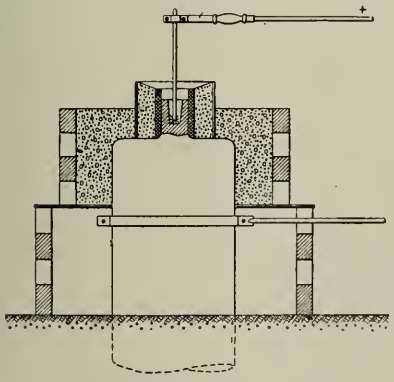

FIG. 5.—REPAIR OF FIG. 1 BY ELECTRIC WELDING.

the quantities of molten iron required for large repairs are considerable and that the handling of such large quantities is difficult and dangerous. (The old burning-on method is specially applicable for cast-iron repairs; for steel welding it offers greater difficulties.) The burning-on method is further restricted, however, to places where the necessary appliances are available, like foundries and machine works. Since this condition is often not fulfilled where a repair is to be made, the electric, thermit, oxy-acetylene, and oxy-hydrogen welding processes have been developed.

Electric Welding.—The chief disadvantage of electric welding is that it requires an electricity supply. Mr. Lamberton describes the Slavianoff process of electric welding, which is used in the works of Julius Pintsch, in Fuerstenwalde-on-the-Spree, in Germany. It is used there especially for the repair of broken locomotive cylinders, and is stated to give quite satisfactory results.

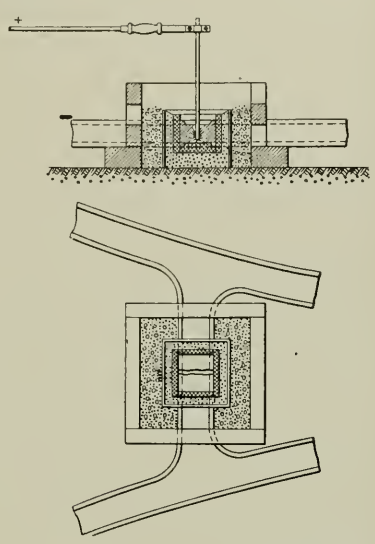

FIG. 6.—REPAIR OF BROKEN FRAME BY ELECTRIC WELDING.

An electric arc is formed between the piece to be welded and a rod of cast iron or steel (of the same composition as the piece to be welded). The method is clearly evident from Figs. 5, 6 and 7.

Fig. 5 corresponds to Fig. 3, showing the movable iron or steel rod which is connected to the positive pole of the circuit. It is 8 mm to 10 mm thick (5/16 in. to 13/32 in.). The piece to be

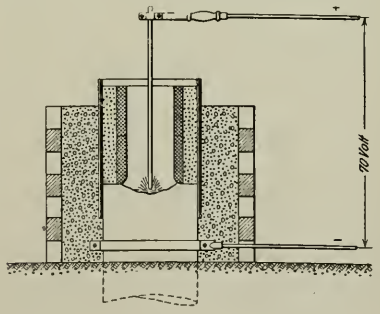

FIG. 7.—REPAIR OF ROLL BY ELECTRIC WELDING.

repaired is enclosed by pressed coke plates, surrounded by the molding sand in a sheet-iron box. The box is surrounded by charcoal or coke within walls of firebricks put together so as to leave open spaces. After the piece has been preheated by the charcoal or coke, the arc is produced by bringing the lower end of the iron rod in contact with the surface to be welded.

In Fig. 6, which corresponds to Fig. 4, it is necessary to enlarge the fracture so that the two surfaces to be welded are at a

distance of 20 mm to 30 mm (13/16 in. to 1 3/16 in.) from each other. The two surfaces are now heated to fusion temperature (beginning at the bottom), while fused iron drops off from the lower end of the rod *a* and unites with the metal of the two surfaces.

Since considerable heat is produced during the welding operation, it is possible to add cold iron in small particles. This is of special importance in Fig. 7 (corresponding to Fig. 5), where considerable quantities of iron are required to make the new boss. Of course, molten iron may also be added if it is available. Mr. Lamberton thinks a repair like that of Fig. 7 could not be well carried out by this process without the use of molten metal.

During the welding operation, especially when molten iron is added, it is important to keep the surface of the joint free from slag or other impurities to ensure a good union with the liquid metal. This is accomplished by repeated scraping off with an iron rod.

Direct current is used at 65 volts; the current is 400 amp to 600 amp according to the thickness of the iron rod *a*. The iron rod must be held during the welding operation so that the arc length is not more nor less than, say, 10 mm (25/64 in.). This requires skilled workmen. They hold the welding rod *a* by means of a pair of tongs, as shown in the illustration, and regulate the arc length by raising or lowering the rod.

Compared with the simple old fusion process of welding, the electric welding process gives a much stronger weld. This is probably due to the fact that no gases can form as the result of an oxidation process, so that the metal gets a very dense structure.

The above electric welding process has not been introduced into this country to our knowledge, although electric welding has been developed here to a large extent. It is used, however, in this country, not for making all kinds of repairs of castings, but rather in such cases where a manufacturer has thousands of

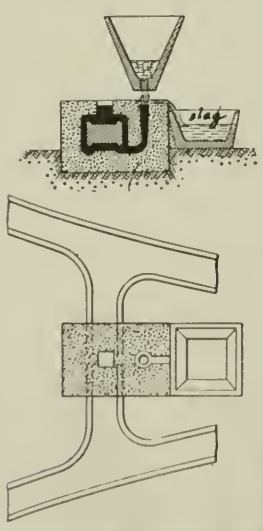

FIG. 8.—REPAIR OF BROKEN STANDARD WITH THERMIT.

pieces of the same kind to weld. The Thomson Electric Welding Company, of Lynn, Mass., has been the pioneer in this field. Their process is especially adapted for making a joint in solid sections, where an end of the piece, round or square, is abutted against the end of another piece of corresponding section, also for T-pieces, etc. Another development of their process is the welding of sheet metal surfaces together in spots, or so-called "electric riveting." The process of the Thomson Electric Welding Company is also employed by the Electric Welding Company, of Pittsburgh. Other processes of electric welding are employed by the Toledo Electric Welding Company, Toledo, Ohio, and by the Standard Welding Company, of Cleveland, Ohio. But as this article is purposely restricted to a comparison of welding methods for the repair of castings, a discussion of the above electric welding methods is reserved for a special article in a future issue.

Thermit Welding.—The thermit welding process makes

$$Fe_2O_3 + Al_2 = Al_2O_3 + 2Fe$$

setting free a large amount of heat and producing very hot molten soft steel. The only requisites are thermit (a mixture of metallic aluminium and iron oxide), and besides this a small

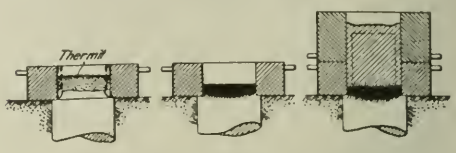

FIG. 9.—REPAIR OF ROLL WITH THERMIT.

amount of ignition powder, which, when lighted with a match, produces the required very high temperature to start the reaction. This process can, therefore, be carried out everywhere, since thermit can be easily transported, being neither explosive nor ignitible at any but very high temperatures.

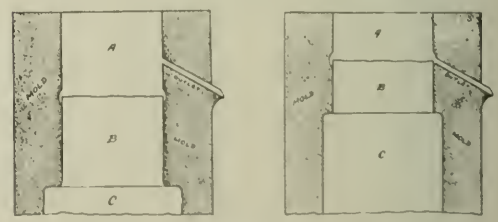
Since the thermit welding process, as carried out by the Goldschmidt Thermit Company, of New York, has been the subject of many articles in former volumes of this journal, no further description is here necessary. But it will be interesting to describe how, according to Mr. Lamberton, the typical repairs of Figs. 2, 3 and 4 are carried out with thermit.

For the removal of blowholes (Figs. 1 and 2) thermit is ignited in magnesite crucibles; the very hot molten metallic iron collects at the bottom, while the alumina slag floats on top. The slag is removed. The molten iron is carefully skimmed of any slag particles (by means of a clean iron rod to which any slag particles adhere) and is then poured into the hole of Fig. 1, *B*.

The welding of two broken machine parts is carried out as shown in Fig. 8 (corresponding to Figs. 3 and 6). The illustration is self-explanatory. To get a perfect weld, the section at the joint is enlarged so as to weld a collar around the joint, and thus strengthen it.

The welding of a boss to a roll by means of thermit according to German practice is shown in Fig. 9, which is easily understood.

It should be added that in the first two cases the joint is no



FIGS. 10 AND 11.—REPAIR OF ROLLS BY THERMIT.

longer cast iron, but thermit iron (soft steel). In special cases of cast-iron repairs this may be a disadvantage, but it is not necessarily so under ordinary conditions, so that Mr. Lamberton concludes that this particular point is not of importance.

Thermit is rarely used pure. Generally iron filings or steel scrap (about 5 per cent to 10 per cent) are added. These are thoroughly cleaned and are added to the crucible before the reaction is started.

With the thermit process it is also important to observe the same precautions of preheating and slowly cooling, described above. Large, solid pieces, which are liable to internal stresses on account of their form, must be preheated with special care. For this purpose a small transportable coke oven is often used abroad, while American practice prefers a gasoline torch operated with compressed air.

In other respects American practice does not differ from the above description of the operation of the thermit process with respect to the first two examples, namely, the removal of surface defects and the welding of two broken machine pieces. As to the third example, it may be said that the repair of broken rolls by thermit is used very extensively in this country, and the general practice is as follows:

In cases where a boss is entirely broken off the thermit process is simply used for the purpose of bringing the fractured surface of the roll to fusing heat, so that a new end may be burned on without difficulty. To accomplish this the roll is placed on the ground in a vertical position and a mold constructed of molding sand, thoroughly dried, is placed about the fractured end. This mold should be provided with an outlet or skim gate 8 in. above the fractured surface. Some steel works prefer to place this skim gate on a level with the fractured end, but it is better practice to locate it higher up. (Figs. 10 and 11.)

A quantity of thermit figured at the rate of 40 lb. to the square foot of surface to be welded is then placed in the mold and ignited. The heat of the reaction raises the temperature of the fractured surface to the fusing point and makes it possible to "burn-on" a section of metal to replace that broken off. This is accomplished by pouring in hot steel from the ladle suspended over the top of the mold as soon as the thermit reaction is completed. In the case of a cast-iron roll, molten iron is used instead of steel.

The pouring is continued until all traces of thermit steel and slag have been washed from the welding surface, when the outlet is plugged up and the mold filled to the top with metal. The waste used in washing off the surface is caught in a suitable receptacle and used to pour small castings.

After the weld has cooled it should be annealed by bringing the roll up to a temperature of 1200° Fahr. and holding it there for five or six hours, after which it is allowed to cool down slowly.

Rolls up to 44 in. in diameter have been successfully repaired in this way, and the process has also been used in welding on sections of steel to the shafts of large pinion gears. The cost of any of these operations, including thermit, labor, annealing and machine work, amounts to only a fraction of the cost of a new roll or shaft. The method of constructing the molds, as recommended by the Goldschmidt Thermit Company, of New York, is shown in Fig. 10 where *A* is the mold for boss, *B* the fractured end of the boss, and *C* the roll. A somewhat different arrangement, which is used by some American steel companies, is shown in Fig. 11.

Oxy-Acetylene and Oxy-Hydrogen Welding.—This method depends on the high temperature which is obtained in the oxy-hydrogen flame (about 4000 deg. Fahr.), and the even higher temperature obtained with the oxy-acetylene flame (about 6300 deg. Fahr.). The possibility of bringing the burner easily to the point to be welded, and, further, the fact that in repairing broken machine parts the welding operation proceeds gradually from point to point along the line or surface to be welded, are the main features of the process. The latter feature is of great importance, especially for repairs of curved surfaces, if pieces are broken out, as happens occasionally. A very interesting application of the process is the repair of broken gas-engine cylinders, which is difficult with other methods.

The repairs shown in Fig. 3 are made with the oxy-acetylene or the oxy-hydrogen flame by first chipping off pieces from both sides of the fracture so as to form a V-shaped opening. This is then heated and the V-shaped opening is filled carefully with uniform iron or steel particles. Then the welding with the oxy-acetylene or oxy-hydrogen flame begins, and care must be taken that the two surfaces of the solid pieces themselves become fluid, so that they combine firmly with the added material.

In cast-iron repairs a difficulty may be found in the affinity of cast iron for oxygen, so that the molten cast iron may get covered with an oxide film during the welding operation. Further, small globules may form at the joint and prevent the flowing together of the original surfaces with the added metal.

The easiest remedy in such cases is the use of one of the commercial fluxes, but not pure borax, since this may easily cause hardening of the joints.

To carry out such work requires a certain amount of skill and experience on the part of the operator. It is also of importance that the same material should be subjected only once to the welding process, since otherwise it may get hard and brittle. As to the material to be added for making the weld, a soft charcoal iron, low in carbon and as free from sulphur as possible, may be used.

The cost of the process is exceedingly low, but depends in such a degree on the greater or smaller skill and experience of the workman that reliable figures cannot be given. The main item of cost is doubtless the cost of preheating the piece to be welded. The other repairs described above may be made in an analogous way.

Like the thermit process, which has made rapid progress during the last five years in this country, the oxy-acetylene process has also made remarkable advances in the United States, especially during the past few years. There are quite a number of different companies interested in this process. The chief differences between the various processes occur in the types of burner employed, the types of acetylene generators used, and the method of producing oxygen..

Among the companies making oxy-acetylene apparatus in this country are the American Oxygen Company, of Philadelphia (formerly the American Ferrofix Brazing Company), the Beltzer-Delcampe Welding Company, of Bridgeport, Conn.; the Davis-Bournonville Company, of New York City; the Industrial Oxygen Company, of New York City; the Linde Air Products Company, of Buffalo, N. Y.; and the Worcester Pressed Steel Company, of Worcester, Mass.

These companies use differently designed blowpipes, the chief point of the design always being the provision of means by which both a perfect control of the flame and a thorough mixture of the two gases in easily adjustable proportions are realized. (The properly adjusted oxy-acetylene welding flame is neutral in character; *i.e.*, neither oxidizing nor reducing, except in very special circumstances with special alloy steels. The final regulation of an oxy-acetylene flame is always made by its appearance, gage adjustment being merely an approximation.) It is customary to make a distinction between low-pressure and high-pressure blowpipes, according to the pressure at which the acetylene is supplied to the burner. Both systems have certain advantages. A typical example of a high-pressure torch is that of the Davis-Bournonville Company, while low-pressure torches are those of the Industrial Oxygen Company, Linde Air Products Company and American Oxygen Company. However, a description and discussion of the different torches is reserved for a special article in a future issue.

As to the generation of acetylene, there are also quite a number of generators on the market, all based, of course, on the reaction between calcium carbide and water. A distinction may be made between water-fed and carbide-fed generators, according to whether water is fed into carbide or carbide into water.

An even greater variety exists in the methods of producing oxygen employed by the different companies.

The Davis-Bournonville Company, of New York City, use the chloride of potash process. A mixture of chloride of po-

tassium and manganese dioxide is placed in a retort and heat is applied. Thereupon the oxygen gas is given off.

The Industrial Oxygen Company, of New York City, employs an electrolytic product called "oxygenite," in the form of a gray pulverulent mass, resembling fine sand, releasing, when incinerated in a closed vessel, all the oxygen it contains, amounting to about 5¼ cu. ft. per pound, burning slowly and without flame.

The H. W. Dopp Company, of Buffalo, N. Y., use lavoisite, which is a dry and non-combustible powder made by the Castner-Electrolytic Alkali Company, of Niagara Falls. Water is added to lavoisite, thus causing an evolution of oxygen gas, 1 cu. ft. of oxygen per pound of lavoisite.

The Roessler & Hasslacher Chemical Company, of New York City, make a compound called oxone (fused sodium peroxide), which in contact with water produces very pure oxygen.

The Worcester Pressed Steel Company now get their oxygen compressed in cylinders, but formerly used the epurite process, epurite being a mixture of chloride of lime, sulphate of copper and sulphate of iron. Oxygen was produced by the contact of this material with water.

The Beltzer-Delcampe Welding Company use a compound called oxyvite.

The American Oxygen Company make their oxygen by a secret process.

While all the above methods make use of chemical reactions for the production of oxygen, an entirely different process is used by the Linde Air Products Company, which gets the oxygen gas from atmospheric air by liquefying the air and by fractional evaporation of the liquid air, thus separating the oxygen from the nitrogen.

Finally, oxygen is made by electrolysis of the water by the American Oxhydric Company, of Milwaukee. This is the only American company using the oxy-hydrogen instead of the oxy-acetylene welding process on a large scale and making oxy-hydrogen welding appliances. This concern compresses oxygen and hydrogen to tanks and supplies the gases in this form to their customers.

An oxy-hydrogen burner made by the Buffalo Dental Manufacturing Company, of Buffalo, is for use by lead burners for constructing and repairing all kinds of lead work, but this blowpipe is not suited to the brazing of iron and steel.

As noted above, a more detailed description of the different oxy-acetylene and oxy-hydrogen methods of welding is reserved for a future article.

Comparison of Different Welding Methods.—In summing up his discussion of the use of the different welding methods for the repair of gray iron castings, Mr. Lamberton reaches the following conclusions.

In foundries he pleads that the old burning-on process should not be superseded entirely by the new methods; the first consideration should always be whether the old process can be used. If a repair is unsuccessful, it would not be right to blame the burning-on process itself, since one cannot be sure that the repair would have been successful if carried out by another method. The new methods also require quite a good amount of skill and car (and we would add that the skill required for oxy-acetylene, oxy-hydrogen and electric welding is the skill of the mechanic, while the skill required for thermit welding is the skill of the foundryman).

Mr Lamberton thinks that for repairs of gray iron castings the old burning-on process has the advantage of a lower temperature, the internal stresses have a much better opportunity to equalize, while the piece to be welded is better preheated by the use of the very large quantities of molten iron.

Nevertheless, foundries should make use of the new methods where they offer advantages. For small and special repairs, Mr Lamberton thinks that the oxy-acetylene or oxy-hydrogen flame is advisable, although, partly at least, they may also be made by electric welding. Repairs of medium size he recommends to make by the old burning on method. For large repairs a combination of the old burning-on process and the thermit process is the only feasible method; the thermit is then used for the purpose of preparing and liquefying the solid surface, while the fused cast iron which is added produces the final union (being of the same composition as the piece to be welded).

Outside of foundries and repair shops, of course, the old burning-on method cannot be used, because the appliances are not available. For emergency repairs on docks, on board ship, in mines, etc., one of the newer methods must be employed. Mr. Lamberton then recommends the making of small repairs by oxy-acetylene or oxy-hydrogen welding, and the making of medium and large repairs by the thermit process.

Mr. Lamberton finally remarks that the equipment for oxy-acetylene or oxy-hydrogen welding is cheap enough while the thermit process requires no equipment at all besides the crucible and thermit. The electric process requires electric power, and cannot, therefore, be used everywhere. But the process yields an especially strong weld, and managers of those plants which have electric current available should acquaint themselves with this method. In conclusion, Mr. Lamberton says that the cost of the heat is approximately the same in the different processes, so that the choice of one of them should be based on the conditions of each case.

Wisconsin Research Fellowship.—Two engineering fellowships, each worth $400 a year, have been established by the regents of the University of Wisconsin. These are in addition to three graduate scholarships already offered in the College of Engineering, and will give still further impetus to the research work at that institution. This year thirty graduate students are doing advanced work in the research laboratories in the testing of materials, particularly of reinforced concrete; hydraulic problems; electrochemistry and chemical engineering. Some of the results of these researches have been published in seven bulletins of the university engineering series.

Refractories in Furnace Construction.

In the excellent little treatise recently issued by the Harbison-Walker Refractories Company, of Pittsburgh, Pa., on the open-hearth furnace and process, a concise summary is given on the principal refractories used, especially in **open-hearth bottoms,** both in the acid and the basic process. The summary, however, is of much broader interest, and in view of the prominent position of the Harbison-Walker Refractories Company in the manufacture of refractories for general and special purposes, these notes are here reproduced in full.

Acid Materials.

The only acid material used is **silica** sand, all acid furnace bottoms being made from it. A natural sand is often used containing various percentages of silica, a typical analysis being, for instance:

Water	0.24	per cent.
Silica	97.25	" "
Alumina and iron oxide	0.16	" "
Lime	0.08	" "
Magnesia	0.39	" "
Alkalies	0.36	" "
Loss on ignition	0.36	" "

Certain beach sands give very good results, and there are also a number of deposits in the West and Middle West, but it is impossible to predict by analysis alone the quality of a given sand. If of excessive purity there is difficulty in properly setting it in the furnace, and if the impurities run too high, although the sand will then easily frit or set, it is subject to great erosion in the operation of the furnace and will not make a sufficiently hard, dense bottom.

The physical characteristics have a wide bearing on the question of its adaptability, and two sands of practically identical analysis may considerably differ as to their suitability for bot-

tom work. Often a combination of two or more sands will secure the best results.

Neutral Materials.

Carbon, while almost perfectly resisting the action of the slag, is very rapidly destroyed on account of the great affinity of the metal for it. It has often been tried in the form of brick, as well as rammed with tar, and, although the matter is again and again reviewed by those not familiar with previous experiments, its practical use is out of the question for open-hearth bottoms. (As to the use of carbon, carborundum and silico-carbides as refractories for electric furnace construction, see, for instance, the article by F. A. J. FitzGerald, our Vol. II, page 441.)

Bauxite, a hydrous oxide of alumina, analyzing approximately:

Silica, SiO_2	4 to 7 per cent.
Iron peroxide, Fe_2O_3	3 to 5 " "
Alumina, Al_2O_3	60 " "
Water, H_2O	30 " "

although exceedingly refractory, is subject to excessive shrinkage at furnace temperatures. It is very difficult to so calcine as to entirely eliminate this shrinkage, and when so calcined all plasticity is lost through loss of its combined water. In modern open-hearth practice it is never used.

Chromite, a sesqui-oxide of chromium, usually termed chrome ore, which has been rather more thoroughly tried out abroad than in this country, is extremely infusible and practically neutral, but its infusibility renders it very difficult to set or sinter thoroughly, and is has been found practically impossible to so thoroughly set the bottom that it will not be subject to mechanical erosion rather than any chemical reaction. It will analyze as follows:

Sesqui-oxide of chromium, Cr_2O_3	38 to 40 per cent.
Alumina, Al_2O_3	24.5 " "
Iron peroxide, Fe_2O_3	17.5 " "
Silica, SiO_2	3.25 " "
Magnesia, MgO	15 " "

In spite of its high refractoriness it has, when selected with due regard to its analysis, and when properly prepared, a large and rapidly widening field in daubing and patching around the slag line, back walls, ports, jambs, etc.

Of course, a neutral bottom would be the ideal one for open-hearth practice, inasmuch as any change from the basic to acid process, or *vice versa,* could be made without change in the furnace; but as indicated above, the materials at our disposition do not allow a satisfactory neutral working bottom.

Basic Materials.

Lime, or calcium carbonate, $CaCo_3$, is, in its calcined form, CaO, theoretically an excellent material for bottoms, but it is practically out of the question due to the rapidity with which it slakes when exposed to air. When reheated, the rapid driving off of the gas and water reduces the lime to a powder, in which condition it is rapidly worn away.

Dolomite, a magnesian limestone, is one of the materials very commonly used for patching bottom, and in some cases even for the entire bottom particularly by those to whom its comparatively low first cost appeals, but it is open to the same objection as lime, only in a lesser degree, *i.e.,* slaking on exposure to the atmosphere, and if a stock is more than 10 days or two weeks old this becomes an important factor. Of course, when the plant calcines its own dolomite this is a less important consideration. Furthermore, it is impossible to so set a dolomite bottom that it shall be as dense and vitreous as magnesite, and in spite of most watchful care portions of the bottom will from time to time become detached and float. In a dolomite bottom where, through erosion or absorption of metal, a hole or depression is once started, disintegration progresses with much more rapidity than with magnesite, and there is considerably more liability of serious breakouts. A fairly representative analysis of dolomite is as follows:

Silica	5.52 per cent.
Alumina and iron	3.74 " "
Calcium	29.20 " "
Magnesia	17.31 " "
Loss on ignition	43.82 " "

In a number of instances the absorption of the impurities from the dolomite has proved an exceedingly serious matter in the manufacture of high-grade steels and has resulted in an increased use of magnesite. Dolomite sets somewhat more rapidly than magnesite.

Magnesium carbonate ($MgCo_3$), when calcined to the oxide MgO, commercially known as magnesite, is unquestionably the best material for open-hearth bottoms, and all original bottoms are now installed with it. Even by those using a large percentage of dolomite in repairing it is admitted to be the best material available, absolutely the only argument in favor of dolomite being its low first cost. The well-known Austrian magnesite of the following approximate analysis

Silica, SiO_2	2.84 per cent.
Alumina, Al_2O_3	0.929 " "
Iron peroxide, Fe_2O_3	8.571 " "
Lime, CaO	1.120 " "
Magnesia, MgO	85.32 " "
Carbon dioxide, CO_2	0.50 " "

gives such a proportion of iron, etc., as makes the material set in the furnace bottom, forming a hearth of maximum density, subject to minimum erosion by the metal and practically unaffected by the slags. Furthermore, on indefinite exposure to the atmosphere almost no deterioration takes place, while with a dolomite bottom under like conditions, should furnace shutdown occur, the bottom would of necessity be renewed. The large deposits of Austrian magnesite insure ample supply for years to come.

Grecian magnesite has been used as a bottom material, but on account of its high refractoriness there is difficulty in fusing it in place, it being necessary to introduce impurities in the way of silica, clay, or oxide or iron in amounts sufficient to reduce its refractoriness. The resultant is too variable a quantity to give reliable results, and Grecian magnesite is very seldom employed.

A Novel Type of Dryer.

In view of the interest shown in the articles on drying in recent issues of this paper, and in view of the great importance of this class of apparatus in many metallurgical and chemical processes, the following brief notes on a recently perfected dryer which operates on a somewhat novel priciple should prove interesting.

The fundamental idea of this dryer, built by the Atlas Dryer Company, of Cleveland, is that of bringing into direct contact with the material to be dried a greater quantity of heated air than is possible with the usual form of cylindrical rotary dryer.

The manner in which this is done is clearly shown in Figs. 1 and 2. From the basic idea of drawing the heated gases through a screen and through the material to be dried was evolved the sectional cylinder, Fig. 1, so designed that the hot gases and air can be drawn through the periphery and into direct contact with the material, the latter being kept constantly "cascading" by the vanes or lifting blades, shown in Fig. 2, as the cylinder rotates in a clockwise direction when viewed from the furnace end. The inclination of the cylinder, of course, keeps the material moving longitudinally.

The cylinder, as will be seen from the illustrations, consists of six curved sections held together by six channel irons running the entire length of the sections. In the channels are slotted openings for the admisison of the heated air and gases. By reference to Fig. 2 it will be seen that there are six broad curved lifting blades directly opposite and inside the openings in the channel irons; these perform the dual duty of guarding

the air passages, thus preventing the drying material from falling out, and of lifting and cascading the material. The broad blades are assisted in the latter function by the small lifting blades.

A casual consideration of such a cylinder with peripheral openings of considerable size is apt to lead to the impression

FIG. 1.—SECTION OF DRYING CYLINDER.

that the material within the cylinder will, in operation, fall through the openings. A study of Fig. 2, either imagining it to rotate or actually rotating it in a clockwise direction, will show how this is impossible. Take the air inlets at the bottom and right of the view; they are cut in a surface which is in a radial plane; as it rotates under and to the left, material from the blades already up on the ascending side does not commence to fall into the "pocket" formed between the blade and the channel iron until the radial plane of the web of the channel is well past the vertical and the openings, consequently, at the upper side of the "pocket." Material from the small lifting blades does not fall into the larger until that plane is almost horizontal, hence none of the material can leave the cylinder.

In the equipment shown in Fig. 3 the furnace is coal-burning, with a mechanical stoker *F* driven from the rotating mechanism. This stoker is furnished with the dryer. By making changes in the furnace gas any other fuel may be used

In the comparatively short time that these dryers have been on the market they have been operated with a great degree of success in gunpowder plants, cement works and for glass manufacturing and paving work, where they handle large quantities of sand, gravel, etc., up to 200 tons per 10-hour day. Chemicals which will stand a moderate degree of heat, and, in fact, nearly everything which can be dried without vacuum is suitable "feed" for this dryer.

The method of installation of the dryer is shown in Fig. 3. The cylinder is surrounded by a steel casing, into which pass the heated air and gases from the furnace. An exhaust fan *E* draws the heated air through the openings into the cylinder, through the falling material within, and out at the exhaust. Set along the base of the casing are doors *G*, which may be opened if desired to reduce the temperature of the air and gases from the furnace before their delivery into the cylinder. The relief stack shown in Fig. 3 is used in starting the fire—if solid fuel is used—to carry off the smoke until the furnace is hot, and when the dryer is shut down.

In the instance of a large provision and packing company this dryer replaced another, modern type with a resulting increased capacity of more than 140 per cent. Sixteen pounds of water were evaporated per pound of combustible consumed on the stoker bars, and tankage, blood and bones were dried without deterioration, without blowing out dust and without danger of fire, as stated by Mr. W. M. Cummer, of the Atlas Dryer Company, Cleveland, Ohio, to whom we are obliged for much of the information in this article.

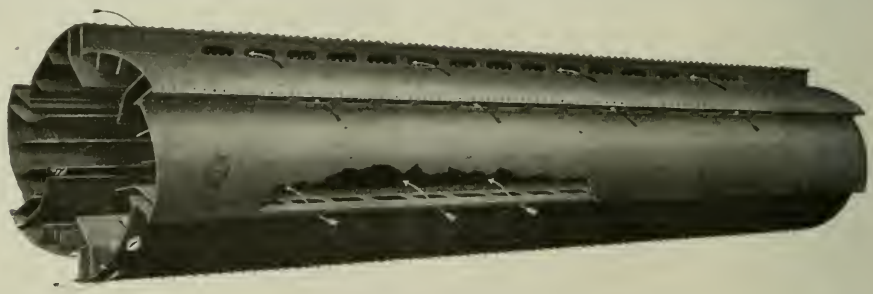


FIG. 2.—PERSPECTIVE OF DRYING CYLINDER.

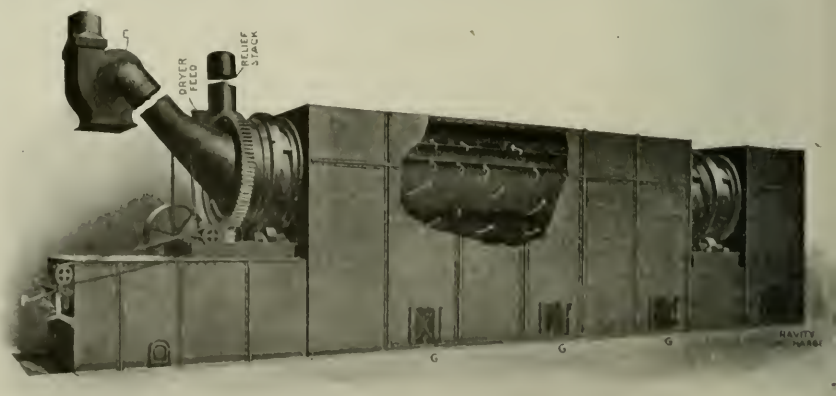

FIG. 3.—DRYER COMPLETE

In this dryer the hottest gases are brought in contact with the wettest material, which is fed in at the furnace end. The further the gases go from the furnace, the cooler they become and the drier also is the material with which they come into contact. The location of the exhaust blower at the front end gives the strong suction where the material is wet and heavy, and permits of a gradual reduction of pressure to practically zero at the discharge end, where the dried material is light.

Successful practical operation has demonstrated that material does not leak out of the cylinder nor is it drawn out as dust in the exhaust.

Production of French Bauxite.

The composition and properties of red French bauxite were described in our November issue (Vol. VII, page 497). During the last three years there has been shipped by the French company handling the product, an average of 46,000 tons of bauxite per year. In the two years preceding this period the shipments only reached 32,000 tons per year. Orders have been received calling for the shipment of 60,000 tons during 1910.

Not only has the amount of bauxite mined during the past five years equaled the tonnage shipped, but it has exceeded it, and the owners now have on hand, either in warehouses or at the mines, a ready stock of 400,000 tons.

The Continental-American Ore Company, of 33 Broad Street, Boston, Mass., are the American agents for this bauxite.

Notes.

Electric Steel Plant.—While the 15-ton Heroult electric furnace of the U. S. Steel Corporation at South Chicago has been in continuous operation since last summer, the second Heroult furnace of the same capacity at the Worcester works has been started in January, and is reported to work very satisfactorily. While at South Chicago the electric furnace is used for refining molten bessemer steel, open-hearth steel is electrically refined at the Worcester plant. The product is used chiefly for steel wire.

Contract for Girod Furnace.—C. W. Leavitt & Company announce that they have closed their second American contract for the installation of a Girod electric steel refining furnace.

Proposed Chemische Reichsanstalt.—Considerable interest has been created in the German chemical world by the decision to form an Imperial Chemical Institute. This institution is to undertake for the chemical industry similar functions to those which the Imperial Physical Institute performs for engineering. The undertaking is being subsidized by the State, and it is expected that the annual maintenance will cost about $10,000.

Cornell University is giving a course of lectures on industrial chemistry by practising chemical engineers. As part of this course Dr. John E. Teeple, of New York City, recently delivered five lectures on the manufacture of sulphuric acid.

Engineers' Society of Western Pennsylvania.—The thirtieth annual meeting of the Engineers' Society of Western Pennsylvania was held in the rooms of the organization, Pittsburgh, Jan. 18, Mr. E. K. Morse, who succeeded to the presidency on the death of George T. Barnsley in October, presiding. The annual report of the board of directors, including the reports of committees, sections and the treasurer was read, indicating the general prosperity of the society during the past year. The membership of the society at the close of the year was 835. The following officers were elected for the ensuing year: President, E. K. Morse; vice-president, J. O. Handy; treasurer, A. E. Frost; directors, A. R. Raymer, Willis Whited.

Western Society of Engineers.—As the result of a letter ballot the Western Society of Engineers has elected the following officers: President, John W. Alvord; first vice-president, O. P. Chamberlain; second vice-president, A. Bement; third vice-president, W. K. Hatt; treasurer, Albert Reichmann. W. W. Curtis is elected a new member of the board of trustees, and the retiring president, Andrews Allen, becomes an ex-officio member of the board of direction.

Mining Institute of Scranton.—This organization ended its year on the evening of December 23 by holding its annual banquet at Scranton, Pa., with a large attendance. Superintendent Phillips, of the Lackawanna Railroad, Superintendent Jennings of the Pennsylvania Coal Company, Prof. A. H. Welles, and Superintendent William H. Allen, of the Scranton Coal Company, were the speakers.

Canadian Mining Institute.—The twelfth annual general meeting of the Institute will be held in the city of Toronto, March 2, 3 and 4. The headquarters will be at the King Edward Hotel. Among those who are expected to prepare papers are: H. F. Bain, Dr. A. E. Barlow, P. McN. Bennie, William Brewer, R. W. Brock, H. P. H. Brumell, Colin St. G. Campnell, Thomas Cantley, Fritz Cirkel, J. M. Clark, Eugene Coste, Dr. James Douglas, John A. Dresser, F. W. Gray, Allan Greenwall, R. E. Hore, Frederic Keffer, J. D. Kendall, Thomas Kiddie, Frank E. Lathe, B. B. Lawrence, R. H. Richards, Dr. Heinrich Ries, Edgar Slansfield, W. J. Woolsey and H. H. Yuill. H. Mortimer Lamb, Windsor Hotel, Montreal, Quebec, is the secretary of the Institute.

Examinations in Chemical Technology.—The Council of the Institute of Chemistry of Great Britain and Ireland will arrange to hold examinations in chemical technology in April. The examinations will be open only to Fellows and to those associates who have been registered as such for at least one year who produce evidence of practical technological training.

The Chemical Society of London, in honor of the completion of fifty years' fellowship by their past presidents, Sir Henry Roscoe, Sir William Crookes, Dr. Hugo Müller and Dr. A. Vernon Harcourt, will entertain them at a dinner of the society to be given some time near the end of May or the beginning of June.

New South African Engineering Institution.—The first annual meeting of the South African Institute of Electrical Engineers was held recently under the chairmanship of Mr. J. R. Bradley. Applications for membership were received from 158 persons, of which 71 have been elected members, 65 associate members, 14 associates and 8 students. Mr. C. M. R. Campbell was elected president, and Mr. W. Eldson-Dew and Mr. M. Rohman were elected vice-presidents.

The French Academie des Sciences have awarded the Hébert prize to M. Paul Janet for his work on alternating currents covered in the new edition of his "Leçons d'Electricité," the Hughes prize to M. Meslin for his work in optics and allied fields, and the Gaston Planté prize to M. Jean Perrin for his work on cathode rays.

Electric Process Quartz Vessels.—A company with a stock capital of 200,000 marks has been organized for the erection of works at Biebrich am Rhein to manufacture quartz vessels (fused silica) by the electric furnace process.

The Hardinge Conical Mill Company of New York City has established a tentative branch office at 415 Bailey Building, Seattle, Wash. Mr. V. G. Lunt, former secretary to Mr. Hardinge, is in charge of this branch, which will operate as a special sales office.

Hoisting Apparatus.—The Brown Hoisting Machinery Company, of Cleveland, Ohio, issues a full library of catalogs covering the different forms of machinery made by them. In the list are catalogs dealing with crabs and winches, blast furnace-hoists and stock distributors, buckets and tubs, locomotive-coaling stations, sewer and trench machines, locomotive ore-handling cranes, coal and coke-handling machinery, all-steel window sashes, and "Ferroinclave." This latter is a corrugated roofing which is erected on steel supports and then covered with cement. The circular illustrates several novel uses to which the product may be put, such as the construction of stairs, side-walls, highway bridges, culverts, water tanks, stacks and coal bins. We will deal with some particularly interesting subjects found in these catalogs in a future issue.

Export Office Opened.—The General Fireproofing Company, of Youngstown, Ohio, has opened an export office at 396 Broadway, New York City, in charge of Mr. A. D. Level, who has been for several years with the United States Steel Products Export Company.

The Société électro-métallurgique piémontaise at Ixelles has organized a new company to take up the handling of auriferous ores by the *Froment* process. The capitalization has been set at 2,500,000 francs.

Cyanide Plant Opens.—The old mill of the Natividad y Anexas Mining Company in the Sierra Juarez district, State of Oaxaca, Mexico, has been closed down and the ores will be treated by the new cyanide plant, which has just been finished.

Bonus for Ethyl Alcohol Plant.—The citizens of Parry Sound, Ontario, have voted a by-law to loan $30,000 to the Union Iron Works for the establishment of an iron-working plant, and also a $10,000 bonus for the erection of an ethyl alcohol plant.

A large Carbide works will be erected in Darfe in Camonicatal by the Aktien-Gesellschaft Ferriere di Voltri. The factory is situated favorably in a very good limestone district which is also rich in water-power.

New Factories.—Carl Zeiss and Company are building a large factory at 29 Margaret Street, London, E. C. The London chemical firm of Allen & Hanbury, Limited, is erecting an extensive plant at Hull.

Passaic Steel to Operate Again.—The property of the Passaic Steel Company, sold recently under the direction of the Chancery Court, has been taken over by a corporation composed of members of the bondholders' committee, and will be operated under the name of the Passaic Structural Steel Company. The new corporation paid $400,000 for the plant and $80,000 to the city of Paterson, N. J., for back taxes. The works were sold by the Passaic Rolling Mill Company to the Passaic Steel Company a few years ago for $1,800,000.

Aluminium.—The British Aluminium Company of 109 Queen Victoria Street, London, has issued a folder giving full particulars, resistance weights, and the like, of standard aluminium conductors ranging in size from 0.000924 sq. in. to 1.0606 sq. in. in cross-section, in comparison with the most nearly equivalent sizes of copper conductors. This comparison serves to show that the aluminium conductors weigh but half as much as copper conductors of equal capacity.

Metallurgical Apparatus.—Among the products of the Patterson Foundry and Machine Company, of East Liverpool, Ohio, of interest to metallurgists and chemists are grinders and pulverizers, filter presses, engines and pumps, and elevating and conveying machinery. A small size filter press built along the lines of the standard "Patterson Round Rail" press and a line of small grinding cylinders are made specially for laboratory use.

Gasoline and Distillate Hoist.—The R. Kelly Machinery Company, of Los Angeles, Cal., recently placed a new gasoline and distillate hoist on the market. The engine is of the marine type and is built in units of 10-hp each. If additional power is required it can be obtained by adding extra cylinders. The hoist can readily be taken apart for the purpose of transportation, and where desired the base and sides are made of one solid casting, insuring the greatest possible strength.

Hopkins Fumeless Zinc Process.—A company has incorporated in Great Britain with a capitalization of $45,000 under the name of the Hopkins Fumeless Zinc Process Company. The purpose of the concern is to acquire and turn to account any improved processes for smelting zinc, especially that process covered by the patents of Reverend E. H. Hopkins. In this issue is an article fully describing the process.

Crucible Firm Organized.—The North British Crucible Company, Limited, has been incorporated in England to manufacture crucibles and like products. The capitalization is fixed at $25,000 and the address registered is 24 Blythswood Square, Glasgow.

Rustless Metal Organization.—The Rustless Metal Company, Limited, has been incorporated in England with a capital of $10,000. Of this $7500 is issued as common and $2500 as preferred stock.

Purifying Water with Ozone.—The United Water improvement Company, of Philadelphia, issues a pamphlet arranged in rather popular form describing their process for the purification of water by ozone. The ozone, electrically produced, is brought into close contact with, and partly dissolved in, water divided into a foamy consistency in the pipes arranged for the purpose. By this means it is said that the ozone combines with the carbon constituents in the pathogenic organisms, thus destroying them. The company lists apparatus in all sizes, from the small installations for domestic use up to municipal plants.

Oxy-Acetylene Welding and Cutting.—The great convenience of the oxy-acetylene process of welding iron, steel and other metals, even aluminium, is now so well recognized that it is being introduced into many factories and repair shops. It is rapidly replacing riveting in sheets up to ½ in. thickness, since it is less expensive, more efficient, and gives neater results. For cutting iron or steel plates the oxy-acetylene burner is much more rapid than pneumatic tools, punches or shears. It is, therefore, not surprising that there are now quite a number of concerns in this country furnishing oxy-acetylene apparatus. We have just received the catalog of the American Oxygen Company, 430 Perry Building, Philadelphia, Pa. It illustrates their torch, special features of which are said to be the method of mixing the gases, the regulation of the oxygen gas by a shut-off cock in case of flash-outs. Their acetylene pressure generator withstands a pressure of 50 lb. But the working pressure is given as 12 lb. The company has an oxygen plant in Camden, N. J., for the production of 10,000 cu. ft. of oxygen daily. While they furnish oxygen gas in high or low-pressure tanks, they are also developing a small portable oxygen generator for use at such places which are too far away from their oxygen-supply station.

Additional Power Installation.—On January 1. the Virginia (Minn.) Electric Power & Water Company began the operation of the additional power apparatus, which has just been installed by the Allis-Chalmers Company. The new apparatus consists of a 37-kw, low-pressure turbine direct-connected to a 2300-volt, 60-cycle, three-phase alternator. The turbine receives steam at a pressure of 16½ lb. absolute and a 28-in. vacuum is maintained by a Tomlinson type "C" condenser. Provision is made for supplying the steam ordinarily from the exhaust of a reciprocating engine, but in case of necessity high-pressure steam can be supplied direct from the boilers through a reducing valve.

Reconstruction of Works.—The American Platinum Works, of 251-255 New Jersey Railroad Avenue, Newark, N. J., have acquired by purchase the real estate and building formerly owned and occupied by the Caffrey Leather Company and J. Liebstein & Sons, located at 225, 227, 229 and 231 New Jersey Railroad Avenue, Newark, covering half a block on that avenue (110 ft.) and having a frontage of 250 ft. on Oliver Street and 30 ft. on Chestnut Street. The present buildings will be reconstructed and modernized and additional structures will be erected, which, when finished, will give this company one of the most complete plants in the world for the refining of platinum, gold and silver.

Addition to Plant.—The Northern Engineering Works, builders of "Northern cranes," Detroit, Mich., have purchased additional land adjoining their plant on which they are preparing to make extensions of their crane plant.

Power from Exhaust Steam.—The fact that only a small portion of the available energy in steam is turned into work by engines when exhausting to atmosphere, and that reciprocating engines are not adapted to operate with high vacuums has caused considerable investigation lately as to the best methods

of getting more work out of the steam. . The method of using a low-pressure turbine working on the exhaust of a high-pressure reciprocating engine has lately come into use. However, in the majority of cases, the amount of steam exhausted by the engine is not proportional to the amount of steam needed by the turbine. This is especially true in the case of rolling-mill engines, hoisting-mill engines, etc., where the exhaust is intermittent. A new apparatus, known as a regenerator, has recently been put on the market for absorbing any surplus steam and storing it up to use in the turbine when the exhaust supply ceases. A booklet entitled "Power from Exhaust Steam," published by the American Regenerator Company, Monadnock Block, Chicago, Ill., goes into this subject quite fully and shows by calculations how the maximum amount of available energy in exhaust steam can be turned into useful work. There are also diagrams showing the comparison of efficiencies of various combinations of reciprocating engines and steam turbines.

Addition to Hydroelectric Plant.—The Portland (Ore.) Railway, Light & Power Company is again increasing the capacity of its hydroelectric plant. It has recently placed an order with the Allis-Chalmers Company for a 3750-kw waterwheel type, 11,000-volt, 60-cycle, three-phase, 360-r.p.m. alternator. This will be of the same general design as the two 2500-kw, 11,000-volt, 33-cycle alternators already supplied by the same company, and will be semi-enclosed. A 50-kw, 120-volt exciter will be direct-connected to an extension of the alternator shaft.

Gold in New York State.—Mr. John M. Clarke, New York State geologist, recently made a report to the Legislature dealing with the supposed gold sands of the Adirondacks, which have attracted so much attention from promoters and prospectors. He concludes that while they contain traces of the precious metal, they do not afford any basis for mining enterprises. "While deficient in the precious metals, the Adirondacks region possesses the elements of large mineral wealth. Its production of iron ores, talc, garnet, graphite, pyrite, and building and monumental stones of various character is a very important contribution to the mineral output of the country. There is abundant opportunity for future development of such resources, and it is in that direction rather than in the seeking of the precious metals that energy and capital can be best employed."

Combination of Firms.—The Trent Engineering Company, composed of the firms of L. C. Trent & Company, of Salt Lake, and the Trent Engineering Company, of Reno, Nev., having combined, have opened a branch office in Los Angeles, Cal., for the extension of its business and for the better convenience of its clients.

Foundry Supply.—Among the catalogs received at our new Pittsburgh office may be mentioned catalog No. 37 of the J. D. Smith Foundry Supply Company, of Cleveland, Ohio. The book is quite complete and covers foundry supplies of all kinds, facings and general equipment. Standard natural draft crucible ovens, core ovens and core-making machines are worthy of special mention.

Dependable Engineering Specialties is the title of the fully illustrated catalog No. 9 of the Wm. Powell Company, of Cincinnati, Ohio, which covers a great many types of valves, globe, gate, check, blow-off and throttle, as well as cocks, lubricators, injectors, whistles and other details. A number of tables of useful information are included. Metallurgists who have in operation steam or gas engines will find this catalog convenient.

Metallurgical Machinery.—Among the most complete sets of catalogs we have received is an assortment from the Wellman-Seaver-Morgan Company, of Cleveland, Ohio. Two general divisions are treated and are outlined in two little illustrated booklets: I. "What We Do in Iron and Steel Works Machinery, Etc." II. "What We Do in Mining and Power Machinery." Each field is covered by catalogs on various specialties, such as open-hearth and reheating furnaces, charging and manipulating apparatus, cranes, buckets, gas producers, reversing valves, hoisting engines and electric hoists, cages and ore cars, tube and ball mills, concentrators, etc. The publication on "Ore and Coal Handling Machinery" is worthy of special commendation.

Sherarduct.—A number of circulars from the National Metal Molding Company, of Pittsburgh, Pa., announce their product "Sherarduct," an iron pipe conduit rendered non-corrosive by sherardizing. This process of galvanizing has frequently been mentioned in these columns and, it will be recalled, consists of enclosing the cleaned metal, together with zinc and zinc oxide dust, in a chamber which is then heated to about 600° Fahr. The zinc alloys, with the iron and a coating of pure zinc, remains on the surface. The United States Sherardizing Company, of New Castle, Pa., owns the American patents and has given licenses to several companies which are now "dry-galvanizing" a variety of articles.

Gas Producers and Valves.—A couple of artistic catalogs from the Forter-Miller Engineering Company, of Pittsburgh, Pa., describe their specialties, water-seal gas producers and water-seal reversing valves, together with open hearth, crucible, reheating and annealing furnaces built by this firm.

The Buckeye Engine Company of Salem, Ohio, has issued a trio of publications. The first deals with steam engines in different forms in sizes up to 8000 hp, while the second treats of four-cycle gas engines from the small sizes to the heavy twin double-acting tandem engines of 6000-hp capacity. The comparisons between thermal efficiencies of steam and gas engines and the typical analyses of various power gases are instructive. "The Sun That Never Sets" is a neat booklet on the Buckeye blue printing machine.

Small Gas Engines.—In the gas-engine field, a field of constantly growing importance in the iron and steel and general metallurgical industries since the more universal introduction of the gas producer, might be mentioned publications of the Foos Gas Engine Company, of Springfield, Ohio. This concern appears to specialize in engines of small and moderate size, say up to 150 hp. The machines are four-cycle, single-acting; the horizontal type has one, and the vertical two, three, or four cylinders. "Foos Junior" equipments are made in from 2-hp to 8-hp units.

Electric Control Apparatus.—From the Pittsburg office of The Electric Controller and Manufacturing Company comes a set of folders illustrating their line of magnetic brakes, motor starters, controllers, magnetic switches and solenoids, electric fault finder, and the well-known lifting magnets. This company has adapted its products particularly for the iron and steel industry, and has now a great many successful installations to its credit.

Laboratory Materials.—A valuable reference book for purchasing agents, chief chemists, and college professors is the catalog of the Scientific Materials Company, of Pittsburgh. The list is remarkably complete and includes some 3000 different forms of apparatus used in chemical laboratory work, each one of which is listed in all the sizes ordinarily used. With the alphabetical classification and the 2000 illustrations accompanying the descriptions, no difficulty is experienced in rapidly locating anything desired.

Additional Catalogs Received.—Among the publications received at our Pittsburgh office which it is not possible to review this month are bulletins from the Lincoln Electric Company and the Triumph Electric Company on small motors and generators; the Bruce-Macbeth Engine Company and the Miller Improved Gas Engine Company, on gas engines; William B. Scaife & Sons Company, on high-pressure tanks and water filters; the Bickford Firebrick Company, and the Grasselli Chemical Company.

Personal.

Mr. **John Fritz**, of Bethlehem, Pa., has been elected an honorary vice-president of the Iron and Steel Institute of Great Britain.

Mr. **Philip Argall** announces that in order to give prompt attention to his rapidly increasing business, he entered on Jan. 1 into partnership with Mr. Philip Henry Argall, late of the Selby Smelter, and Mr. George Oates Argall, general manager of the Iron Silver Mining Company, of Leadville, Col., with the purpose of conducting a general business as consulting, mining and metallurgical engineers, under the name of Philip Argall & Sons. The offices of the firm are in the Majestic Building, Denver, Col.

Dr. **Ernst J. Lederle,** consulting sanitary engineer for the New York City Board of Water Supply and a member of the New York State Water Supply Commission, has been appointed commissioner of the New York City Health Department. Dr. Lederle occupied the position before, during the Seth Low administration, beginning in 1902.

Mr. **G. H. Dowell,** who for a number of years has been employed by the Phelps-Dodge interests at the Douglas, Ariz., smelter, has been appointed general manager of the Old Dominion. Mr. George Kingdon, who has been acting superintendent since the resignation of Mr. R. B. Hegardt some time ago, will henceforth be superintendent of mines, and also general superintendent of the United Globe property controlled by the Old Dominion Copper Mining and Smelting Company.

Mr. **E. B. Raymond,** who has been General Superintendent of the Schenectady works of the General Electric Company, is leaving that concern to enter the employ of the Pittsburgh Plate Glass Company in the position of second vice-president. Mr. Raymond is a graduate of the Massachusetts Institute of Technology, class of 1890.

Mr. **Donald G. Miller** is doing engineering work at Pilares de Nacogori, Sonora, Mexico, for the Montezuma Copper Company.

Mr. **Fred B. Crosby** has left the power and mining department of the General Electric Company to take up a position as technical writer with the publication department of the Westinghouse Electric & Manufacturing Company.

Mr. **Frederick H. Keyes,** formerly general manager of the Robb-Mumford Boiler Company, on Jan. 1 associated with Messrs. T. W. Sprague, H. D. Jackson and others to carry on a general consulting engineering business. The offices of the firm will be at 88 Broad Street, Boston.

Mr. **Arthur A. Brown,** formerly manager of the Pittsburgh office of the Westinghouse, Church, Kerr Company, recently accepted a position in the sales department of the Westinghouse Electric & Manufacturing Company. Mr. Brown's headquarters will be in New York City.

Mr. **George C. Vivian** has severed his Utah mining connections, and has returned to Colorado, where on Jan. 1 he took charge as manager of the Golden smelter of the North American Smelter & Mines Company.

Mr. **W. D. Healy,** formerly of Detroit, Mich., has entered the employ of the Union Pacific Cobalt Company as manager.

Mr. **A. B. Emery** has been appointed assistant general manager of the Southern Division of Mexico Mines of the American Smelters Securities Company. Mr. R. E. Adams succeeds Mr. Emery as superintendent of the Velardeña district. Mr. W. M. Drury has been appointed assistant general manager of the Northern Division of Mexico mines of the company.

Mr. **Andrew McFarland,** of Colorado, has taken charge as general superintendent of the Lucia Mining Company, Gabrial, Durango, Mexico.

Mr. **C. M. Eye** has resigned as manager of the Benguet Consolidated Mining Company, at Bagulo, Philippine Islands, to take charge of the Colorado Mining Company at Aroroy, in the Island of Mashate His successor with the Benguet company is Mr. Amos W Cole, recently with the Oriental Mining Company, in Korea.

Mr. **Kamajiro Kajiura,** engineer for the Besshi Copper Mines Company, at Nuhama, Iyo, Japan, has been in this country recently studying the smelter fume and smoke problem. His company is operating its smelter on an island 10 miles from the coast of Japan, but even at that distance is having trouble with the farmers on the mainland, who complain of the fumes as a nuisance.

Mr. **I. Wayne Von Leer,** of New York, has been appointed manager of the Arizona United Mining Company, at Johnson, Ariz.

Mr. **Frederick N. Pease,** Assistant Chemist of the Pennsylvania Railroad has been appointed chief chemist to succeed the late Dr. Charles B. Dudley.

Professor **Theodore W. Richards,** of Harvard University has been reappointed research associate of the Carnegie Institution. With the appointment he receives a new grant of $2,500 to enable the continuation of his researches regarding atomic weights and physico-chemical constants. At the last meeting of the Chemists' Club, of New York City, which was in the form of a Harvard night, Professor Richards was made an honorary member of the club.

Dr. **Rudolph Messel** has been appointed Honorary Foreign Secretary of the Society of Chemical Industry to take the place of the late Dr. Ludwig Mond. Professor A. Liversidge, F.R.S., has been appointed a vice-president of the society, succeeding Dr. Mond.

Dr. **L. F. Guttman,** formerly of the chemical department of the College of the City of New York, has been called as assistant professor of chemistry to Queen's College, Kingston, Ontario, Canada.

Mr. **W. M. Tattersall** has been appointed keeper of the Manchester (England) Museum, to succeed Dr. W. E. Hoyle.

Professor **J. Culver Hartzell** has resigned as head of the department of geology and chemistry at the University of the Pacific. The resignation is to take effect at the close of the present academic year.

Dr. **Albert P. Sy** has become director of the chemical laboratories and professor of chemistry at the University of Buffalo, succeeding Dr. H. N. Hill, resigned.

Dr. **Austin M. Patterson** has been elected Editor of *Chemical Abstracts,* to succeed Dr. W. A. Noyes. Mr. John M. Miller becomes associate editor.

Dr. **Henry M. Payne,** who recently resigned his position as professor of mining engineering at the University of West Virginia, has been appointed field manager of the Hydraulic Mining Cartridge Company, of 42 Broadway, New York City.

Dr. **Benzo Katsura,** Professor of Metallurgy in the Imperial Tokio (Japan) University, was a recent visitor to the United States and made a tour of the metallurgical plants of the country. He secured many publications for the University library.

Dr. **J. L. Simonsen,** assistant lecturer and demonstrator in the chemical department of the University of Manchester (England), has been called to the chair of professor of chemistry at the University of Madras (India). Dr. A. Holt takes the place left vacant by Dr Simonsen at Manchester.

Dr. **G. Gürich,** docent in the department of geology at Breslau, has been appointed director of the Geological Institute at Hamburg, to succeed the late Professor Gottsche.

M. **Emile Picard** has been chosen president of the Paris Academy of Sciences for 1910. The place he formerly held as vice-president will be filled by M. Armand Gautier.

Dr. **Charles Graham,** formerly professor of chemical technology at the University College, London, has bequeathed his residual estate, which is estimated to amount to $175,000, to the college for research in the School of Advanced Medical Studies at the University of London.

Dr. **Ernst J. Berg** is now head of the electrical engineering department at the University of Illinois, having left the General Electric Company to take up this new position. He is a native of Sweden, receiving his education at the Royal Institute of Technology, Stockholm, graduating in 1892, and coming at once to America. While with the General Electric Company

he became chief assistant to Dr. Steinmetz. For the past two years he was Consulting Professor of Electrical Engineering at Union University. Recently he received the degree of Sc.D. from that institution

Tau Beta Pi.—The twenty-third chapter of Tau Beta Pi, the honorary engineering fraternity, was installed at Cornell University on Jan. 17, by Professor L. E. Moore, assistant professor of civil engineering at the Massachusetts Institute of Technology, and president of the fraternity.

The **Society of Sigma Xi** held a business meeting and banquet in Boston on the afternoon and evening of December 29, on the occasion of the meeting of the American Association for the Advancement of Science.

Phi Lambda Upsilon.—There is now at Columbia University a chapter of the honorary chemical fraternity, Phi Lambda Upsilon. Its faculty members are Profs. C. F. Chandler, M. T. Bogert, J. L. R. Morgan and H. C. Sherman. Mr. J. B. Barnitt is president of the chapter, Mr. Charles Crew is vice-president, and Mr. Robert Schwarz secretary-treasurer.

American Electrochemical Society

Seventeen applicants were elected to membership in the American Electrochemical Society at the meeting of the board of directors of that organization held in Philadelphia on Friday, Dec. 31, 1909. Announcement is made that the next meeting of the society will be held in Pittsburgh the latter part of April.

The list of new members elected follows:

Messrs. Augustus H. Eustis, Mining Engineer, Boston, Mass.; Walter L. Badger, Chemist, Great Western Sugar Company, Brush, Col.; William S. Barwick, Chemist and Metallurgist, The Vancouver Engineering Works, Vancouver, B. C.; Charles E. Skinner, Engineer, Research Division, Westinghouse Electric Manufacturing Company, Wilkinsburg, Pa.; George M. Colvocoresses, Superintendent, Millerett Silver Mining Company, Gowganda, Ontario; Lorain E. Imlay, Superintendent, The Niagara Falls Power Company, Niagara Falls, N. Y.; Harold Binney, of Binney, Mastick and Ogden, New York City; James D. Pickard, Mechanical Engineer, The Colorado Vanadium Company, Boulder, Col.; Edgard de Souza, Chief Electrical Engineer, The S. Paulo Tramway Light and Power Company, Ltd., S. Paulo, Brazil; C. H. Bowman, President, Montana State School of Mines, Butte, Montana; Jorge Newbery, City Electrical Engineer, Buenos Ayres, Argentine Republic, S. A.; Frederick H. Loveridge, Electrical Engineer, Western Electric Company, Chicago, Ill.; T. K. Armachela, Assistant Engineer, Public Works Department, Mysore Government, Bangalore, S. India; Floyd D. Taylor, Student of Electrochemical Engineering, The Pennsylvania State College, State College, Pa.; Herbery F. Sill, Assistant Professor of Chemistry, Carnegie Technical Schools, Chemical Dept., Pittsburgh, Pa.; Bradley Stoughton, Consulting Electric Furnace Engineer, New York City; William J. Cummings, C. E., Chief Engineer, E. I. DuPont Powder Company, Haskell, N. J.

American Chemical Society

The following have been elected to membership in the American Chemical Society.

Clive M. Alexander, Iowa City, Ia.; Edward X. Anderson, Iowa City, Ia.; Joseph C. Andrews, Ithaca, N. Y.; Olney P. Anthony, Norwood, Mass.; Eli H. Armstrong, East Point, Ga.; Philip S. Beebe, Columbus, Ohio; O. W. Boies, Ithaca, N. Y.; Thomas Roland Briggs, Ithaca, N. Y.; James Brown, Alcalo, Ill.; Guiseppe Bruni, University of Padua, Padua, Italy; J. R. Bryce, Ithaca, N. Y.; William McG. Burns, Boston, Mass.; Howard N. Calderwood, Jr., Lawrence, Kan.; R. S. Callaway, Minneapolis, Minn.; Horace H. Clark, Chicago, Ill.; Albert D. Conley, Orono, Maine; L. S. Cozzens, Freeport, N. Y.; L. J. Cross, Ithaca, N. Y.; H. A. Crown, Ithaca, N. Y.; Raphael Dennery, New Orleans, La.; Miss Mary V. Dover, Mount Holyoke College, South Hadley, Mass.; Carl Englund, Vermilion, S. D.; J. Clifford Evans, Millville, N. J.; Edgar M. Flint, New York City; William R. Flint, New Haven, Conn.; H. J. Glück, Ithaca, N. Y.; Benjamin H. Harrison, Champaign, Ill.; Ellwood Hendrick, New York City; J. J. Hinman, Jr., Indianapolis, Ind.; August Holmes, Reno, Nev.; Arthur E. Houlehan, Ithaca, N. Y.; J. W. Humphrey, Lawrence, Kan.; Vasco Hunez, Ithaca, N. Y.; W. Lawton Iveson, Toronto, Canada; José Jauer, New York City; R. L. Jones, Nashville, Tenn.; Forrest W. Kehoe, Great Barrington, Mass.; Theodore B. Kelly, Berkeley, Cal.; William J. Kelly, Leipzig, Germany; James Kewley, Balik Papan, East Borneo; W. A. Koenig, Philadelphia, Pa.; Herbert G. Kribs, Philadelphia, Pa.; David Mauson, New York City; A. O. Mason, Ithaca, N. Y.; W. H. Maynard, Knoxville, Tenn.; H. G. McCoy, Ithaca, N. Y.; Cyrus L. Merriam, Santa Lucrecia, V. C., Mexico; James Hill Miller, Dublin, Ireland; Harry W. Morse, Cambridge, Mass.; J. E. Myers, Albany, N. Y.; James H. Pettit, Urbana, Ill.; W. L. Rar, Madison, Wis.; Barleigh B. Reed, Iowa City, Ia.; Harold E. Riegger, Ithaca, N. Y.; Joseph Rosin, Philadelphia, Pa.; Miss Jennie L. Rowell, Burlington, Vt.; Harvey Schackelford, Columbia, Mo.; C. Silver, Ithaca, N. Y.; Arthur Smith, Toronto, Canada; Erwin Sohn, Cleveland, Ohio; Walter A. Sperry, Columbus, Ohio; Fred C. Stewart, Portland, Maine; Harry M. St. John, Ithaca, N. Y.; F. W. Stockton, Lawrence, Kan.; S. Sutker, Gadsden, Ala.; Edward Tapp, Chicago, Ill.; Claude S. Tingley, DeLand, Fla.; W. F. Walker, Mulberry, Fla.; Harry V. Welch, Berkeley, Cal.; LeRoy F. Whipple, Kingston, R. I.; R. A. Winser, Aurora, Ill.; Malcolm G. Wyer, Iowa City, Ia. The Procter & Gamble Company, of Cincinnati, Ohio, and the George A. Schmidt Company, of Chicago, Ill., were admitted to corporation membership.

NEW BOOKS.

MORGAN, J. LIVINGSTON RUTGERS. Physical Chemistry for Electrical Engineers. Second edition, revised. 259 pages, illustrated. Price, $1.50. New York: John Wiley & Sons.

NAGEL, OSKAR. The Transportation of Gases, Liquids and Solids by Means of Steam, Compressed Air and Pressure Water. A complete description of the theory, construction, operation and application of jet machines, montejus, spray nozzles, etc., for chemical, metallurgical, mining, mechanical and civil engineers, with 193 illustrations. 212 pages. Price, $2.00 net. New York: Oskar Nagel (P. O. Box 385).

THORPE, Sir E. History of Chemistry. In two volumes. Vol. 1. From the earliest times to the middle of the nineteenth century. 217 pages. Price, 75 cents net. New York: Putnam.

ALLEN, ALFRED H., M. D. Commercial Organic Analysis. Fourth edition. Vol. 1, introduction. Alcohols, yeast, malt liquors and malt, wines and spirits, neutral alcoholic derivatives, sugars, starch and its isomerides, paper and paper-making materials, vegetable acids. Edited by Henry Leffman and W. A. Davis. 586 pages. Price, $5.00 net. Philadelphia: P. Blakiston's Son & Company.

LEACH, ALBERT ERNEST. Food Inspection and Analysis. For the use of public analysis, health officers, sanitary chemists and food economists. Second edition, revised and enlarged. 972 pages, illustrated. Price, $7.50. New York: John Wiley & Sons.

WATERBURY, LESLIE ABRAM. A Vest Pocket Handbook of Mathematics for Engineers. 197 pages, cloth. Price, $1.50. New York: John Wiley & Sons.

MACLAURIN, RICHARD COCKBURN. Light. Cloth, 257 pages. Price, $1.50. New York: The Macmillan Company.

NAGEL, OSKAR. Producer Gas Fired Furnaces. Cloth, 187 pages. Price, $2.00 net. New York, the author, P. O. Box 385.

BOOK REVIEWS.

The Mechanical World Pocket Diary and Year Book for 1910. 300 pages, price 6d. (Retail price in New York, 25 cents.) Manchester, England: Emmott & Company, Ltd.

This handy little reference book has undergone a number of improvements this year. First of all, it has been reduced in bulk by the use of thinner paper, although considerable new matter has been added.

The gas engine section has been thoroughly revised and a new section on oil engines added. A section on ball bearings and some things on centrifugal pump design have also been added. There are numerous other additions, most of which relate to the construction and design of machine details, such as gears, bearings, etc.

The 300 pages of text are well filled with data condensed in a most concise form. The collection of tables is exceptionally well chosen and will be found most useful to those who have to do with the installation and operation of prime movers.

* * *

The Mechanical World Electrical Pocketbook for 1910 175 pages, price 6d. (Retail price in New York, 25 cents.) Manchester, England: Emmott & Company, Ltd.

This is a companion to the Mechanical World Year Book, and is evidently intended for mechanics and electricians rather than engineers. It contains very short descriptions of various apparatus and gives directions for wiring and installation of apparatus, testing of circuits and making simple measurements. The wiring practice is, of course, that laid down by the British code and does not apply in this country. There is practically no data in tabular form that is not to be found in all handbooks; that is, tables of squares and cubes, areas and circumferences, logarithms, etc. This book is far behind its companion, the Year Book, as a reference book of useful data.

Les Découvertes modernes en Physique. By **O. Manville.** Second edition. 8vo, 462 pages. Price, 8 francs. (Retail price in New York, $2.10.) Paris: A. Hermann et Fils.

The work consists of two parts: the first deals with the relation of electricity and matter; the second with the rôle of ions and electrons in physical phenomena. The first part has chapters on the electric conductivity of liquids, of gases, the ionization of gases, and the electronic theory of matter. The second deals with electrolysis, electric discharge in gases, electric conductivity of metals. A supplementary chapter treats of the modern conceptions of the relations of matter and ether. Our general impression of the work is that it contains a great deal about interesting, modern developments, rather uncritically worked up. Twelve pages of notes and errata (mostly the latter), which the reader is asked to kindly insert at the proper pages (a labor of several hours), complete the volume.

* * *

Analyse Thermique et Metallographie Microscopique. By **E. Rengade,** Docteur des Sciences, Chef de trauvaux, pratiques à la Faculté des Sciences. Cloth, 176 pages, 53 figures and 26 photographs. Price, $1.80. Paris: Librairie Hachette et Cie.

This book is intended for beginners. It has a preface by H. Le Chatelier which clearly sets forth the guiding ideas and topics the book treats of. Solutions, alloys, glasses, solders, rocks, etc., have until recently not been considered worthy of intimate study by chemists. By the newer methods these classes of natural objects have been made the subject of close scrutiny and the methods which this little work describes so tersely and clearly have been introduced into many laboratories. The first portion of the text deals with Gibbs' rule, which is made the starting point for the development of the succeeding chapters. Numerous illustrations add greatly to the elucidation of the topics discussed and at the end there is a chapter on the apparatus and the methods of thermic analysis. The use of the thermo-electric couple is given and apparatus whereby continuous records of the variations of the current can be secured. There is a special chapter on the iron-carbon system.

The second portion of the work is devoted to metallography. This part is illustrated by some excellent micro-photographs. The technical preparation of the metal is given and the simple character of the methods is in strong contrast with the great insight thus obtained into the structure of materials, particularly steels.

* * *

Die Lack und Firnisfabrikation, by Professor **Max Bottler.** 130 pages, 29 illustrations. Price, 4.50 marks. (Retail price in New York, $1.50.) Halle, a. S.: Wilhelm Knapp.

This is No. 16 of a very interesting and valuable series of monographs on chemical, technical and manufacturing methods, edited by Mr. L. Max Wohlgemuth and issued by the publisher, Wilhelm Knapp.

In his preface the author says: "In the industries resting upon chemical bases, the manufacturer of lacquers and varnishes occupies a conspicuous position. In recent years this manufacturer has made important progress, partly in improvement of long known processes, but partly also in wholly new discoveries or processes. In the work before us will be found practical considerations of the newer inventions and technical advances. Special attention is given to the different methods of operation."

The author has well stated the plan and scope of the work. The nine chapters discuss the history of lacquers and varnishes, their classification, the raw materials of the industry, preparatory treatment and generalities, oil varnishes and fatty lacquers, oil of turpentine and benzine lacquers, alcoholic and other "volatile" and "non-volatile" lacquers, coloring, decolorizing and filtering lacquers and varnishes, preparation of printing and lithographing varnishes, soap lacquers, resinate lacquers, and casein lacquers.

Chemists seek in vain for good books in English on this subject, to serve as a guide for those directly or indirectly interested in the industry. For such as can read German this book will prove a boon, and all chemists, whether varnish makers or not, will find it a valuable addition to their working libraries.

* * *

Cost of Mining. By **J. R. Finlay.** 415 pages. Price, $5 net. New York: McGraw-Hill Book Company.

It has ever been the aim of this journal to be broad, to look at the domain of chemical and metallurgical engineering from such a standpoint that things could be seen in their proper perspective, but at the same time to scrutinize the essential details necessary for practical success. In short, we have endeavored to be far-sighted in the right way and to be near-sighted in the right way without being piddlers. This being our aim in technical journalism, we are glad to call attention to Mr. Finlay's "Cost of Mining" because the author attains successfully in his book such a consummation.

Mr. Finlay has achieved success in various fields of human activity. At Harvard, he was noted as an athlete on the field and on the water. Later, after serving his engineering apprenticeship, he has managed successfully mining properties of the first and second magnitude in Cripple Creek, the Cœur d'Alenes, Lake Superior iron district, Joplin, the Flat River district and elsewhere. He has at different times acted as consulting engineer, lectured at Harvard University, and lately assumed charge as general manager of the Goldfield Consolidated Mines Company which is making the largest net profit of any gold property in the world.

Mr. Finlay is a master of lucid English and composition, and has contributed many good articles to the various mining journals. With such all-round ability in the author, little comment is needed on the book.

Mining and metallurgy are closely associated. The first finds the valuable ore and gets it out of the ground. The second takes the valuable ore and turns it into a product that can be sold at a profit. To make a rabbit stew, first catch and skin your rabbit; next be sure you have a fire and a stew-pan in which to prepare the rabbit for the table.

Looked at broadly, the question of cost of mining and treating of ores is of prime importance. For mining and reduction procedures are governed by the principles of economic science as well as by those of natural science and engineering science. Mr. Finlay, we are glad to note, always analyses the subject from the tests of cold-blooded business. This is perfectly proper in a book entitled "Cost of Mining." The evaluation of mining property is first taken up and incidentally a clear light is shed on the warped view that the public takes of mining investments. Next, the cost of development work or finding the ore, and stoping it, raising it, and reducing it is dealt with in a philosophic manner. Finally having laid down certain general principles, the author analyzes, from the viewpoint of these principles, the reports of representative coal, iron, lead, copper, silver, gold and zinc companies.

Many illuminating passages might be cited. On page 11 it is neatly shown how the efficiency of labor varies, being high in hard times and low in good times. The chapter on the U. S. Steel Corporation is especially good. On pages 371-3 a clear exposition is given of the dictum of the first Lord Brassey, a great English contractor, that the same work costs the same money all over the world regardless of the wages paid the unskilled laborer.

Everywhere in the book is seen due regard for the laws of economic science, which to our mind are as far reaching as the law of gravitation, though less immediate in their action.

This book is quite to our liking. It can be recommended alike to the student of finance, to the practical business man, to the mining engineer, to the chemical or metallurgical engineer, or in point of fact to anyone interested in the wresting of mineral wealth from Nature's bosom.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine

Vol. VIII. New York, March, 1910 No. 3

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

239 West 39th Street, New York

Pittsburgh Office, 413 Lewis Block.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

J. W. Richards, Ph.D.....*President*
E. F. Roeber, Ph.D.....*Editor and Secretary*
C. E. Whittlesey.....*Treasurer*

Yearly subscription price for United States, Mexico and United States dependencies, $2.00; for all other countries, $2.50 (European exchange, 10 shillings, 10 marks, 12.50 francs).

Copyright, 1910, by the Electrochemical Publishing Company.

Entered as Second-Class Matter at the Post Office at New York, N. Y., under the Act of Congress, March 3, 1879

New York, March, 1910.

The Eighth International Congress for Applied Chemistry.

On page 118 we print the official report of the preliminary meeting in which the organization of the Eighth International Congress was considered that is to be held in this country in 1912 with Prof. Edward W. Morley as honorary president and Dr. W. H. Nichols as acting president. It is a pleasure for this journal to endorse here fully the sentiment of chemical democracy expressed by Dr. Nichols at that meeting— that the central and vital point to be observed is that every chemist in the United States should feel that he is part of the Congress from the very creation of the organizing committee down through all the details of management to the very close of the Congress and that everything should be done which could in any way contribute to the realization of that thought. We endorse with equal sincerity the other leitmotiv of Dr. Nichols' suggestions "that quality and not quantity should count, that science should count against mere commercialism or ostentatious show." We recommend the official statement on page 118 to the earnest attention and consideration of all our chemical and metallurgical readers.

Ferrosilicon.

The extended article on the manufacture and transport of ferrosilicon, printed elsewhere in this issue, will be found to contain a considerable amount of useful and interesting information. But, we state frankly, that in publishing this information we do not intend or expect to encourage the erection of further ferrosilicon works at present. Up to a few years ago the higher grades of ferrosilicon, which require the use of the electric furnace, were almost exclusively made in Europe. The product came largely from that string of mountain electric-furnace plants, notably in southern France, which had originally been erected for calcium carbide manufacture, but had to look out for some other manufacture when the European carbide boom collapsed. During the last years the manufacture of ferrosilicon has been taken up in this country (which is really the pioneer country of the manufacture of other alloys in the electric furnace) and ferrosilicon is now being made by a large company with works in Niagara Falls, N. Y., and in Virginia, while another company makes metallic silicon in Niagara Falls, N. Y. Besides these there is a Canadian works for manufacture of ferrosilicon, operating in Welland, Ont., while a company which made ferrosilicon on a smaller scale in Lockport, N. Y., has recently discontinued operation due to the market conditions, which have continued to remain unsatisfactory in spite of the considerably increased duty placed on ferrosilicon by the new tariff. This is significant.

* * *

The simple explanation of the continued unsatisfactory ferrosilicon market is, of course, overproduction. When the

manufacture of high-grade ferrosilicon and other high-grade ferro-alloys in the electric furnace was taken up, it offered good profits. Steel manufacturers were also quick to realize the advantages of the high-grade electric furnace alloy, the use of which (in spite of its higher price compared with low-grade blast-furnace ferrosilicon) not only reduces very essentially the amount of undesired impurities (especially carbon) introduced with the alloy into the steel bath, but also has a higher energy content, heating the bath by the oxidation heat of silicon, instead of chilling it. But after all, the demand for high-grade ferrosilicon, as well as for other electric-furnace ferro-alloys, is a limited one in the nature of things. This is especially true, since the one ferro-alloy for which there is a really large market—ferro-manganese—is made almost exclusively in the blast furnace for good reasons which need no discussion at this place. It is not difficult to understand how overproduction came about with the prices of ferrosilicon practically cut in half. Now most of the French works are operating on a largely reduced scale. Of course, time will straighten out matters. The weakest producers will go to the wall and the fittest will survive. Then the new tariff may exert the effect to be expected.

* * *

While we do not know that any serious accidents have happened in this country on account of dangerous gases evolved from electric-furnace ferrosilicon, such accidents have happened in Europe and have attracted a great deal of attention in England. Concerning the nature of the gases and the possibilities of preventing such danger, the article in this issue contains much interesting information. So far the majority of the French manufacturers have agreed on making only certain grades, which are free from danger, while the British Government is likely to issue regulations on the transport of ferrosilicon. All these developments should also be interesting in this country, both for the producer and the consumer.

Cost of Power.

There still exists considerable confusion in the minds of many engineers as to the cost of developing power, especially water-power. Those who are interested in getting reliable and conservative figures on the basis of best modern American practice may be referred to a paper presented by Mr. Henry L. Doherty before the American Institute of Electrical Engineers on Dec 16, 1909; in the discussion of this paper some very valuable figures on the cost of steam-power and water-power were given both by Mr. Calvert Townley and Dr. Cary T. Hutchinson. It is not our intention to go here into the details of those estimates, but we will simply give the following table of Dr. Hutchinson for the cost of energy in cents per kw-hour for steam and water-power plants, a medium-head hydroelectric generating and transmission plant being assumed in the latter case. These values are based on the assumption of a fixed annual charge of $13.60 per kilowatt, plus an output charge of 0.5 cent per kw-hour for the steam plant, and a fixed charge of $20 per kilowatt of demand on the water-power plant. As shown, at a high value of load factor the hydroelectric plant can show a much larger profit than the steam plant, while the profits decrease as the load factor becomes less. In the last column of the table is shown the price, at various load factors, at which energy from the hydroelectric plant must be sold in order to produce a profit of 6 per cent on the investment.

COST AND SELLING PRICE OF ENERGY PER KW-HOUR AT VARIOUS ANNUAL LOAD FACTORS.

Per cent. Load factor	——Cost of kw-hour in cents—— Steam plant.	Water plant.	Selling price, water power.
15	1.54	1.52	2.44
25	1.12	0.91	1.46
33	0.97	0.69	1.10
40	0.89	0.57	0.92
50	0.81	0.46	0.73
60	0.76	0.38	0.61
75	0.71	0.31	0.49

* * *

The above figures, while apparently high, are undoubtedly correct for the average hydroelectric power and transmission plant. Under special conditions where the hydraulic development is easy and no transmission line is required they could be reduced. This will be true for many electrochemical plants which can be located right near the water-power. And the fact that electrochemical plants have a very high uniform load factor makes them ideal customers of the power-plant. Nevertheless, such prices as are reported from Norway—$4 or $5 per hp-year—can never be expected in this country under present conditions. For within the region over which power can be transmitted and distributed economically from the power plant, enough customers can always be found in this country to which power can be sold with greater profits. It is different in Norway. The question is not whether a power plant could generate power at such and such a very low cost, but whether it could sell it to electrochemical customers at so much less a price than it could get from others to whom the power would have to be transmitted over a distance. The margin between the Norwegian price of $4 or $5 per hp-year and the price which can be obtained from ordinary customers is so large that it would pay for quite an extended transmission and distribution system.

Electrolytic Amalgamation.

The notice of a patent for an electrolytic amalgamation process which appears in this issue under Current Metallurgical and Chemical Patents, gives us an opportunity to comment briefly on the probable rationale of this class of novel processes about which much has been heard in a somewhat general way from various parts of the West during the past few years. However the apparatus and the solution employed may differ, all these processes agree in making the amalgamation plate the cathode of an electrolytic cell; and the claim generally made for such processes is that in this way it is possible to recover on the amalgamated plate "floured gold," "rusted gold," and, in general, gold in a condition in which it cannot be recovered in ordinary amalgamation practice. There are three essentially different reasons why such an arrangement may be effective. In the first place, cathodic reduction, which always goes on at the mercury cathode surface, will reduce any oxides, etc., which may have formed on it; further, since in such processes a mercuric salt is generally used in solution, fresh metallic mercury is constantly being precipitated on the amalgamated plate. In this way the surface is always maintained in best condition, ready to alloy with any particles of free gold which come in contact with it. In this respect nothing is changed in the principle of the ordinary amalgamation process; the current simply keeps the mercury plate automatically in perfect condition

A second reason to which the effectiveness of electrolytic amalgamation may be assigned is suggested by some observations on gold telluride ores made by Dr. W. H. Walker and described by him in an American Electrochemical Society paper in 1903. He noticed that electrolytic methods working on this class of ore recover their values in greater part by direct cathodic reduction than they do by first dissolving the mineral in the electrolyte with subsequent precipitation of the gold on the cathode. Good contact with the cathode is, therefore, an essential requirement; for this provision is made in electrolytic amalgamation processes so that particles of ore of the class mentioned, when coming in contact with the cathode plate, are directly reduced by the current and the reduced gold then alloys with the mercury. A third possible effect which will vary with the nature of the solution used is the solution of gold particles in the electrolyte in form of a gold salt with subsequent precipitation of the gold on the cathode; in this respect the process would be like an electrocyanide or an electric chlorination process. From a practical standpoint the great saving in time, obtainable with electrolytic amalgamation, seems of prime importance. While these processes have attracted the attention of some able metallurgists, they have been developed in other places more or less by the rule of thumb. The general activity along these lines would indicate, however, that some concrete results have been obtained and that a distinct progress of lasting benefit to the metallurgical profession will be the ultimate outcome. Naturally, we should expect the new processes to be used on a commercial scale first for the treatment of such ores which offer special difficulties with present practice.

The Primitive Ideas of Some Connellsville Coke Operators.

At a meeting of the American Association for the Advancement of Science many years ago the late Dr. Samuel P. Langley suggested that while it was comfortable to conceive of the advancement of science as comparable with the progress of a large and well-disciplined army, a more truthful simile was that of a disorganized mob, bent on progress, but with groups constantly making sallies in this or that direction, so that at a given time the general trend of movement was hard to discern, although by observations taken at intervals a distinct forward movement of the whole mass could be noticed. A like simile might be applied to progress in the industrial arts. One invention or discovery waits upon another. Perhaps it is our reference just now to Dr. Langley which puts us in mind of flying machines; at any rate, we may observe that 20 years ago he clearly demonstrated the feasibility of mechanical flight, and, indeed, Lilienthal accomplished many "glides" before he met his death in 1889. Yet it was not until recently that perfect mechanical flight was accomplished. The success was really due to the development of a suitable internal combustion engine. Indeed, it is interesting to recall that one of Langley's troubles at one time in conducting his whirling table experiments was that the gas engine erected to drive it would not go.

* * *

Our mention of gas engines brings us to our subject. Twenty years ago efforts were made to introduce by-product coke-making into the United States, but these efforts were not successful. The value of the solid and liquid by-products was recognized, but it was doubted whether those values would be maintained in the face of heavy production. It was not admitted that the gas would have a great value. Naturally, it was not regarded as practicable to pipe it long distances to centers of population, when the much richer natural gas was available for the same purpose. The advent of the large gas engine, together with the means for economically converting the energy it produces into electrical energy, has multiplied by many times the commercial value of gas from by-product coking. The by-product coke oven has really awaited the perfection of means to make useful the gas which it was practically as well able to produce 20 years ago as it is to-day. Unlike the case of tar and ammonia, there is an unlimited market for gas for converting its energy into electrical energy.

* * *

In the past six months the coke operators of the Connellsville region have confessed an absolute ignorance of the developments in retort coking and the use of the by-products. The time was that Connellsville coke was regarded as the only really good blast-furnace fuel. Obsessed with the idea that perforce a much larger quantity of Connellsville coke would be demanded by the iron industry in 1910 than ever before, Connellsville coke operators last September and October pushed the value of their furnace coke to $3 a net ton at ovens, and then waited for the rush of customers. Through the growth of by-product and beehive coking in other fields the proportion of the total blast-furnace trade of the North, which depends upon Connellsville coke, has been reduced, and while the Connellsville operators waited for buyers to step to the counter, provision was made to use other cokes. There has been a tumble in Connellsville coke prices since the middle of January, and the industry now finds itself in the position of having much unsold production, but with no consumers, since their old ones are apparently provided with one coke or another.

* * *

In May of last year Connellsville furnace coke sold on contract for second half delivery at about $1.60 per net ton at ovens. There is no reason to suppose the price was unprofitable. An inspection of cost sheets indicates that at an average operation the cost of production, before the slight advance in wages in January of this year, was about $1.25 per ton, without depreciation and other fixed charges. The pushing of the price to $3 merely on the supposition that blast furnaces would have to pay the price or not make pig iron was a command to the industry to seek other fuel. When another fuel has been found, the consumer does not return to Connellsville. The customer is lost. Connellsville coke operators are anxious now to sell at much lower prices than those demanded late last year, but the business is gone. Report has it that they are now seeking to establish a "central selling agency" so as to maintain uniformly a high price for their coke. When they sell their coke at their own bare cost of production they are selling it for a greater price than it is worth, for they have produced it in the most wasteful and extravagant manner. They have failed utterly to realize that the day of by-product coking is fully arrived. They are exerting a tremendous pressure toward the adoption of modern methods, but they are killing their own business and writing an enormous depreciation upon their coal reserves.

Eighth International Congress of Applied Chemistry.

On the evening of Feb. 3, 1910, an informal gathering took place at which there were present among others most of those to whom had been delegated the task of providing for the creation of an organization for the Eighth International Congress of Applied Chemistry, by the London Congress last June; a representative of the Association of Manufacturing Chemists, the American Chemical Society, the American Electrochemical Society, and the Society of Chemical Industry were each also present at this informal meeting.

The consensus of opinion was that the greatest success could be expected only if the most effective system and mode of organization could be had, and if each and every chemist in the United States could be made to feel that he himself directly or indirectly through his professional, business or educational affiliations, had a personal share of responsibility in the conduct and management of the Congress from its very start and to its very end.

This was regarded as the proper and correct guide in proposing any plans or schemes of organization.

The Eighth Congress is to convene in 1912, with Prof. Edward W. Morley as honorary president and Dr. W. H. Nichols as acting president, at a time and place to be determined by the organization of this Congress. The most important part of the Congress, in fact that by which its value and real success will be measured, is the amount of original matter, both scientific and technical, which it will be able to present to its members.

To attain this end fully every chemist in America who has or may have any original matter to present to this Congress should begin without delay to prepare such matter, and have it in shape so that it may be presented to the Congress in ample time for proper printing, classification, and distribution to members and the technical and scientific press.

The Congress, being held in the United States, will with a great deal of right and naturally look to a very good showing from the chemists of the United States, and every chemist in this country, which is to be host to our foreign colleagues, should constitute himself a committee of one to get from himself, or from his friends, as much scientifically or technically valuable material as possible so that the proceedings and publications of the Eighth Congress may correctly reflect the true mental attitude of the chemists of the United States toward their profession, both as a pure science and as a part of the industrial activities of this country.

It is the hope that the Program Committee will be able to begin its activities effectively before the close of 1910, but in the meantime it behooves every chemist in the United States actively and energetically to consider how and in what way he can best contribute to the success of this Congress, and particularly in the direction of papers and communications to the Congress embodying the advance in this field since June, 1909, the date of the last Congress.

At a meeting to be held in April or May, 1910, by those charged with the duty of providing suitable organization for the Eighth Congress, some definite action as to such organization may be looked for. Those who have that responsibility are making every effort to get as many suggestions as to divisions of organization, mode or organizing, and membership of the organization as possible. Every one interested in having this organization on as broad foundation as possible is earnestly invited to present any suggestions that may be helpful in that direction in writing by the middle of April, 1910, so that all these suggestions may be properly classified and collated and put in condition for most thorough consideration before the meeting above referred to actually takes place.

Such communications may be addressed to the temporary secretary, Dr. B. C. Hesse, 90 William Street, New York City

Bureau of Standards' Analyzed Samples.

The Bureau of Standards, Washington, D. C., is ready to distribute Bessemer steels with 0.6 and 0.8 carbon and an iron C to replace that originally prepared by the American Foundrymen's Association. The new C has the following composition: Total C, 2.78; graphite, 2.22; Si, 1.84; Ti, 0.074; P, 0.192; S by oxid, 0.0354; S by evol., 0.0335; Mn, 0.744.

A new iron B was found to need remixing and partial analysis. It is hoped that the sample will be ready to distribute by the time this notice appears in print.

A vanadium steel and an ore of manganese await the reconciling of differences in the analytical results reported.

Three Lake Superior iron ores are undergoing analysis; one to serve as a standard for iron, phosphorus and silicon; the second for aluminium, calcium and magnesium; and the third for manganese.

Standardization of Bullion and Assay Values.

The Sectional Committee B for the standardization of bullion and assay values of the Institution of Mining and Metallurgy was formed for the purpose of recommending rules which shall, as far as possible, be followed by assayers, metallurgists and mining men in reporting the results of assays and of metallurgical, dressing and other tests of which assays form an essential part, so that ambiguity shall be avoided and the possibility of misinterpretation or misuse of reports shall be minimized. The committee has now submitted to the council of the Institution the following report, which is now to be considered, before being finally adopted.

Reports of assay results, extraction tests, metallurgical and ore-dressing trials, etc., are sometimes so worded as to permit a wrong interpretation, and the committee urges the necessity for definite statements as to the nature and condition of the sample as assayed, and, where advisable, an indication of the method of assay. Thus, in the case of such metals as copper, tin, lead, antimony, etc., where both "wet" and "dry" methods of assay are in use, results should be reported as obtained by "fire" asay or by "wet" assay, with further details as to method, if adjudged advisable. Similarly, it should be stated whether the sample was assayed in the condition in which it was received, or "air-dried" or dried at —° C.

In reporting that an assay for such a constituent as tin, arsenic, tungstic acid, etc., corresponds to so much "black tin," "white arsenic," "wolfram" or other recognized saleable product, the report should give the assay result for such constituent, together with a definite statement as to the figures used in calculating such saleable product. Thus, an assay showing 1 per cent of metallic tin might be reported as 1 per cent of metallic tin, equivalent, if all could be extracted as such, to 1.5 per cent of "black tin" containing 66.6 per cent (or two-thirds) of its weight of metallic tin. Similarly, in reporting results, where assay values might be mistaken as representing available produce, it should be stated that such are merely "gross" assay values, a statement or estimate of the actual "commercial" values being added whenever possible.

In such matters as ore-dressing, ore-treating processes, furnace work, etc., where so much depends on the way in which results are reported, on the nature of the sample and on the method of taking it and its relation to other samples, the committee emphasizes the necessity for careful phraseology and for the inclusion of exact data, as also the necessity for care in preparing, describing, labeling, sealing and otherwise ensuring the correctness and authenticity of samples submitted for tests or assays.

The bullion and assay values committee submit the following recommendations for adoption by the Institution:

(1) Assay reports shall state the exact condition of the sample as to dryness when assayed.

(2) Assay values of gold and silver ores and products shall

be represented in pennyweights and decimals or in ounces and decimals, and not in oz., dwts. and grains. They shall be expressed in terms of fine gold and fine silver, respectively, not as "bullion."

(3) Assay values of alluvials shall be reported in grains and decimals of a grain of "fine"gold, or in pence (at 2d. per grain of "fine" gold), or cents per cubic yard.

It is recommended that, in the absence of specific information, 1 cu. yd. of ordinary alluvial, excluding boulders, be taken as equivalent to 3000 lb. (1½ short tons).

(4) In reporting assay values of cyanide and other solutions, the results shall be given in parts by weight in a stated volume of the solution. (In the case of cyanide solutions, the use of the "fluid ton of 32 cu. ft." is recommended. It closely approximates to 2000 lb. and is in common use.)

(5) When it is necessary to state or estimate the money value of an ore, etc. (other than of gold), it shall be accompanied by the assay value, and the basis on which the former has been calculated from the latter shall be stated.

(6) Laboratory sieving tests shall be made with the I.M.M. standard sieves, or, when other sieves are used, the widths of the apertures shall be stated.

The report is signed by G. T. Holloway as chairman of the committee.

With the above recommendations, if approved, will be included the following, which have already been adopted on the recommendation of the weights and measures sectional committee:

(*a*) The word "ton" shall represent a weight of 2000 lb. avoirdupois (2,166.6 oz. troy). (It is advisable to abandon the use of the terms hundredweights and quarters, and to express fractions of a ton in pounds or in decimals of a ton.)

(*b*) The word "gallon" shall represent the Imperial gallon measure of 10 lb. of water.

(*c*) Temperatures shall be expressed in degrees Centigrade.

(*d*) Returns of gold and silver shall be expressed in terms of fine gold and fine silver, respectively, not as "bullion."

(*e*) Gold contents of ores, etc., determined by assay, shall be expressed in money values as well as in weights; and in this connection the value shall be taken (as a convenient constant) at 85 shillings, or $20.67 United States currency, per troy ounce of fine gold.

The Iron and Steel Market.

February has been a dull month in the market, demand being light all along the line, while prices have definitely receded on pig iron and have shown weakness on a few finished steel products. The market failed to bear out any of the prognostications. In December, when new buying was light by comparison with the six preceding months, opinion was divided as to whether the market would show a decided improvement early in the new year or would merely hold its own. It has done neither; it has lost ground, and has lost more in February than in January.

The American iron trade suffers from a delusion that the hanging of new calendars upon the walls of business offices is an incentive to the placing of orders. Time and again it has staked its all upon the improved business which "the new year" would bring, and as often it has been disappointed. In the late months of 1908 there was a well-defined boom and in all quarters the belief was expressed that this small boom was but the precursor to the big one which the new year would bring, but the new year brought a crash in prices as well. Even when the remarkable period of activity of 1905-06-07 was being ushered in there occurred the delusion of the calendar, for the improvement which occurred in the late months of 1904 was regarded as but the forerunner of a still greater improvement to occur early in 1905, whereas pig iron lost ground almost steadily during the first seven months of that year and steel products would probably have done the same had they not been well held by a trade understanding.

The feature of the trade revival in the second half of 1909 was the uneven distribution of the improvement; merchant steel bars constituted the market leader, carrying with them plates and shapes; wire products did well, and so did sheets and tin plates, while merchant pipe was heavy, the buying being largely because of the low price, jobbers buying for fear there would be an advance and mills fearing to advance prices lest buying should be discouraged. Rails showed almost no movement.

Students of the psychology of market movements may be interested in the influences produced by the different finished steel products being more or less completely under the influence of different systems of selling developed by the respective subsidiaries of the United States Steel Corporation. There are temperamental differences between the managements of the different subsidiaries. The common ground upon which they meet is that of their reports to headquarters of results achieved in tonnage booked. It is not impossible that in the efforts of given subsidiaries to show results comparing favorably with those of other subsidiaries the importance of immediate results is magnified and the importance of providing for the future is minimized. Without attempting to pursue the query at this time, it may be remarked that the result of the operations of the last seven or eight months of 1909 was to leave the different branches of the finished steel trade with orders booked for quite varying distances ahead. Steel bars were sold for nearly six months ahead, plates and shapes for perhaps four months ahead, and pipe and wire for scarcely any distance at all ahead, while jobbers in these two latter lines were more than comfortably stocked. Both by the necessity of physical conditions, since these products are all made from the same semifinished material, and by the temperament of purchasers, who regard the iron and steel trade as an entity and not as a chance group of unrelated elements, the strength of the market as a whole is largely in relation to the strength of its weakest element. Consumers of steel bars are not likely to be enthusiastic buyers for far forward delivery when they observe that prices of wire products are being cut and production is perhaps being curtailed.

Pig Iron.

The spectacular buying of Bessemer pig iron from June to October of last year advanced the market rapidly from $14.50, valley, to $19, a price which was first done Oct. 12, there being altogether more than 100,000 tons sold at that figure. It is an open secret that the large independent steel interests buy Bessemer iron at such times partly because they really expect to need it, partly because they may need it, and partly because such purchases help to improve the market for their finished products. Many contracts for billets and finished steel products are on a scale basis, the price determined by the average selling price of Bessemer pig iron.

It was expected that Bessemer pig iron would draw other grades of pig iron along in the advance, but basic pig iron halted at $17.25, leaving a spread of $1.75 between the grades. In 1905-06 the average spread was about 25 cents and in 1907-08, when Bessemer ores were 25 cents per ton higher relative to non-Bessemer ores, than in the preceding years, the average was about 75 cents. Expectations that basic pig would advance to reduce the spread were disappointed, for in November basic receded to $17 and in December a slight further recession occurred. Toward the close of January it developed that basic could be bought at $16.50, leaving the position of Bessemer at $19 altogether untenable.

There was danger of a break and to crystallize sentiment into a moderate decline the United States Steel Corporation, early in February, bought 40,000 tons at $18, valley, leaving the trade under the impression that upon occasion further purchases might be made. The Bessemer market rests at this. Basic, openly offered at $16.50, valley, has been quietly offered

at $16, and two or three forced sales have been made at slightly lower prices, so that the situation is again involved. In foundry pig iron there have been recessions in nearly all districts.

Virginia furnaces came down to $15 at the furnace for No. 2 plain, silicon 2.00 to 2.50 per cent, and 2500 tons of Southern iron were sold on the basis of $13, Birmingham. In eastern Pennsylvania there were slight recessions. The valley market dropped to $16.25. The total decline from the top point in November has been approximately $2 at Birmingham, $1 in Virginia, 50 cents in eastern Pennsylvania, and $1 in the valley market.

Steel.

The supply of unfinished steel has increased in all districts. Chicago producers have become sellers of forging and rolling billets, having been out of the market for several months. In Pittsburgh and the Central West deliveries of billets and sheet bars have become very good, to such an extent that some consumers have requested shipments postponed. Prices have not openly yielded, but it is improbable that any large tonnages could be sold except at material concessions. There is no demand, consumers being amply covered by contracts. Nominal prices are approximately as follows, f.o.b. maker's mill, Pittsburgh or Youngstown:

Bessemer billets, $27 to $27.50; open-hearth billets, $27.50 to $28; sheet bars, $28.50 to $29; rods, $33.

Strictly new buying of finished steel products has been light. Specifications on old contracts have been fairly good. The steel-car shops are running practically full, booked for four to six months. The fabricating shops are about equally well filled.

The plate and shape mills in the Pittsburgh and in the Chicago districts are comfortable taken care of until about June 1; the Eastern mills have already begun to make concessions of $1 a ton. Demand for ordinary sheets has become light, while specialties are still in demand, particularly electrical and stamping sheets.

Some sheet mills which were extremely optimistic last fall and book little business have not much work in sight, while others are comfortably filled.

Early in January steel bars were quoted by all interests at $1.50, base, the December market having been $1.45 on contract and $1.50 for small, prompt lots. The former position has been resumed, the market being $1.45 on contracts, but it is a position whether this constitutes an actual recession, the minimum of $1.50 not having been absolutely established.

Regular prices, at Pittsburgh, except where otherwise noted, stand:

Standard steel rails, $28 for Bessemer; $30 for open-hearth, f.o.b. mill except Colorado.

Plates, $1.55 for tank quality, ¼ in. and heavier.

Shapes, $1.55 for I-beams and channels, 15 in. and under, zees and angles, 2 x 3 and larger.

Steel bars, $1.45 to $1.50, base.

Iron bars, $1.65 to $1.70, Pittsburgh; $1.55 to $1.60, Philadelphia; $1.55 to $1.60, Chicago; $1.50 to $1.55, St. Louis.

Wire nails, $1.85, base; plain wire, $1.65; galvanized barb wire, $2.15.

Black sheets, 28 gage, $2.40; galvanized, $3.50; blue annealed, 10 gage, $1.75 to $1.85; painted corrugated roofing, $1.70 per square; galvanized, $3.

Tin plates, $3.60 for 100 lb. cokes

CORRESPONDENCE

Iron-Copper Alloys.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—We note with interest Mr George W. Sargent's comments on the paper "Physical Properties of the Iron Copper Alloys." We are realizing full well the limitations of data obtained from experiments conducted on a laboratory scale and under special conditions of working, and it is, therefore, of interest and of advantage to have the opinions of practicing metallurgists regarding the probability of repetition of interesting results from operations conducted on an industrial scale.

We can appreciate Mr. Sargent's statement concerning a lack of harmony between the preface of our paper and the actual work done, and that the two together give an erroneous impression. This is caused, no doubt, by the fact that the article in *Electrochemical and Metallurgical Industry* was only an abstract of the paper presented at the meeting of the American Electrochemical Society. While the report of our experimental work was reprinted practically in full, the introductory matter was necessarily very much condensed.

Our paper points out that the first impressions regarding the presence of copper in steels were that it was decidedly deleterious; that later work showed that small amounts did not have the pronounced detrimental effects usually attributed to copper.

Finally, we quote the experimental data of other investigators, and corroborating our results, tending to the conclusions that additions of copper up to 4 per cent were accompanied by material increase in the tensile strength of the steel.

Mr. Sargent believes that red shortness would be the general result of copper additions, especially in the familiar steel-making processes, due to the oxidizing reactions and the consequent formation of oxides of copper. We do not believe that this contention is supported by chemical facts or metallurgical experience.

These facts are:

Iron will oxidize to ferrous oxide more readily than copper will to cuprous oxide.

Either iron or copper oxide will be reduced by carbon, manganese, aluminium, or silicon, the common deoxidizing agents of steel-making.

Consequently, we should expect that if oxidation of the bath were carried to the extent of formation of dissolved oxides, ferrous oxide would be the first to form, and brittleness would result whether copper were present or not. Again, it is to be expected that the customary additions would have an even greater effect in reducing any copper oxides than they now have on the oxides of iron.

Experience in the metallurgy of copper supports this view. As reverberatory refining of copper is conducted, the iron is oxidized and scorified with the additions of sand. To quote from Schnabel's "Handbook of Metallurgy," Vol 1, page 237: "The separation of these elements (impurities, including iron, lead, zinc, etc.) can be brought about by oxidizing fusion of the coarse copper." "By oxidizing fusion of coarse copper, its foreign constituents (with the exception of the precious metals) can be oxidized (because their affinity for oxygen is greater than that of copper) and slagged off."

It seems likely, as was intimated in our paper, that the unfavorable influences are the effect of increase of carbon on the structural relations of copper and iron, and the affinity of copper for any sulphur which might be present, with the formation of sulphide of copper and its incorporation in the body of the steel.

The Patent Treaty With Germany.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Enclosed please find a translation of a very important recent decision* of the German Reichsgericht (Supreme Court). It refers to the recently concluded patent treaty between the United States and Germany

*An abstract of this is given elsewhere in this issue, in the article entitled "A Reichsgericht Decision on the Scope of the Patent Treaty between the United States and Germany."—Ed.

The Imperial Court interprets this patent treaty in a most liberal way and comes to a conclusion which is causing general indignation among industrial circles in Germany.

The patent treaty in question was concluded because the Committee on Patents of the House of Representatives threatened to introduce a working clause similar to the one of the British and German law into the American Patent law. In order to free the citizens of both countries from the burden of such a working clause the treaty was concluded.

Now, this working clause has not been introduced into the United States Patent law, and there does not exist any reason for such a patent treaty between the countries.

Meanwhile the treaty is exerting its influence in litigations under the German patent law to the greatest detriment—as many interested parties claim—of the industries of the German Empire, and there is a strong agitation to induce the Government to cancel the treaty.

It is pointed out that Great Britain, which peremptorily refused to conclude a similar treaty with the United States, has now the laugh on Germany.

To refer back to the decision, the court decrees that a German owning a German patent is forced to work his invention either in Germany or the United States, while an American owning a German patent needs not work his invention either in Germany or the United States because the country of his nationality does not enforce the working clause.

Consequently, a German owning patents may avoid the working clause by assigning his patent to an American.

MANUFACTURER.

Silundum.

To the Editar of Metallurgical and Chemical Engineering:

SIR:—Professor Tucker's excellent paper on "Silundum," which is in full accordance with the experience obtained in the commercial production of said material, has caused a controversy between Messrs. E. G. Acheson and F Bölling, as well as your editorial remarks in your last issue.

Leaving aside the question of the priority I first only beg to state one fact which possibly might elucidate the matter, and secondly call your attention to the rôle of an element which hitherto has been overlooked by most of the experimenters though often contained in carbon-silicon compounds:

(1) Dr. Acheson says that the heating of carbon, silicon and oxygen may either result in the formation of graphite, silicon or carborundum, or of a compound of all the three elements. No doubt about this. But there are only a relatively small number of analyses existing of siloxicon, and so far it does not seem to be a definite chemical individual. We find in many other cases, too, that a practically useful material such as siloxicon need not possess a uniform chemical composition. There is no reason why it should not be possible to combine the first two elements also in such a way as to form a product of variable chemical formulas. On the contrary, the presence of dissolved carbon and silicon in many metals makes it probable that an alloy of these two elements exists, and that is what silundum seems to be and what further scientific investigation is expected to affirm. It may have spontaneously been formed in some furnaces long ago, yet it had not been discovered.

(2) Among the earliest literature about the reactions of carbon and silicon at high temperatures we find compounds of these elements with nitrogen described. As the coke employed in the carborundum furnace contains nitrogen, there is no doubt that this element, preferably reacting at high temperatures, influences the product of the furnace in a certain way; about the character of this influence we know even less than about that on iron and steel. Nitrogen is found in carborundum as well as in silundum, as stated on another occasion (*Zeitschrift für Elektrochemie*, 1909, p. 727), and I regret that industrial work did not leave me the time to pay the necessary attention to this question.* But if once the binary silicon-carbon diagram will have been devised the further evolution of the Acheson diagram must necessarily take notice of the nitrogen as well as of the oxygen.

CHICAGO, ILL. R. AMBERG.

*The so-called oxygen contents of siloxicon is mostly given as the difference between the total and the silicon and carbon, analytically determined.

The Trust from the Standpoint of an Engineer.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—Your journal has on its editorial page alluded so often to the trust question, both in its general aspects and particularly to the metallurgical trusts, that possibly my views will interest your readers, for I have had business relations with several of the large trusts, and thus have first-hand knowledge. Lately I have read a very remarkable exposition of the economics of the trust question by the Hon. Bourke Cockran in his brief for the American Tobacco Company before the Supreme Court of the United States. This elucidates the theory of monopolies from the standpoint of English common law. My reasoning of the case is along quite different lines, but the end product is in each case the same. Let me say that I hold no brief for the American Tobacco Company, as I usually insist on smoking non-trust cigars.

In the first place, let it be stated that by a trust is meant a large corporation seeking to dominate the market for any one commodity and actually possessing preponderant trade influence in that market. This is the usual definition.

Now the trust is but a natural outgrowth of industrial evolution. We know that evolution is that process by which things grow through countless small processes of differentiations and integrations from the tiny homogeneous units to the large heterogeneous unit. The great contribution of the nineteenth century to the philosophy of the ages was the formulation by Darwin of that doctrine in the biological world and its application by Herbert Spencer to all branches of science. So it is just natural to point to the United States Steel Corporation for instance, as the product of a perfectly natural industrial evolulutionary process. Demagogues may rail at it, at Mr. Carnegie and at Mr. Morgan. But facts are facts. We see the United States Steel Corporation pursuing the even tenor of its way (not, of course, the market value of its stock) and we can only admit that it is a product of the age.

As no one but a simpleton will deny the above argument that the "trusts" are the logical outcome of the natural evolution of industrialism, let us inquire why it should exist in the light of the evolutionary theory. Naturally, it exists because the fittest survive. This is simply tautology. So let us ask why it should survive, or, better, why one trust survives and another goes to the wall. First of all, it can be stated that it exists because the weight of public opinion is on its side. For does anyone suppose that if the mass of people in this country believe all the things said about the Standard Oil Company that it would survive a day? I doubt whether legislative enactments would be used at all, but it would seem probable that physical violence would be rightly used. No! the average of public opinion is that the Standard Oil Company, though far from perfect, is, on the whole, serving a beneficent purpose in the United States. It undoubtedly took rebates, but, you could sweep this wide country and if you can show me 100 small country cross-road grocers that would refuse to accept a reduction of 50 cents per barrel of flour if they handled exclusively one brand, I misjudge human nature. It is just human nature to trade with your friends. And rebating, so common once, is similar to the practice of giving a special favor to your friends.

Now, the trust stands in spite of adverse public opinion of the discontented minority. Why does it sell its goods to this American people, who, though easily fooled for a short time, do

not stay fooled long? Obviously because on the average it produces and sells its goods on quality and price. Against this it may be argued that the Steel Corporation is charging a high price for rails and is making large profits at prices higher than prevalent in Europe. But, without the evidence, let me assume as a fact that steel rails can be produced at a factory cost of $15. This figure is, to the best of my knowledge, about correct. Why, then, do not outside companies step in and erect large plants if profit is so large? There is a multiplicity of causes as in any phenomenon. But the chief reason, in my opinion is that the risk of the business, the value to the community of ore in the ground and other charges reduce the net return on the investment to about 15 per cent. Now, there are so many kinds of smaller manufacturing companies doing a business of from $100,000 to $1,000,000 per year in this country at a profit of greater than 15 per cent that there is not present in the United States the kind of capital that cares to go into the rail business when, for example, the automobile business exists.

If the American people want rails sold at less than $28 per ton, let it subject, by removing the tariff, the rail manufacturers to the competition of Germany, where manufacturing profits are much less.

It can be laid down as a fact that in this country, therefore, there is always plenty of competition if the profits are large enough. As Mr. Cockran well says, "competition may be potential or active."

Now, any trust may fail (and great will be the fall thereof), provided it is managed in an non-progressive, unintelligent and crassly selfish manner. And conversely, a trust will succeed provided it is managed in an up-to-date, intelligent manner and in a spirit of enlightened self-interest. And, furthermore, its degree of success depends upon the measure of intelligence of its management. The same is true of a railroad or any concern of any kind at all. Efficiency spells success. Somehow or other, intelligence seems to win in this world in the long run. In short, intelligently managed concerns, large or small succeed. If the trust makes mistakes, its mistakes are just so much the more costly as the trust is big. And some one of the independents, the one who uses the best intelligently directed head work, will take the first place in the hegemony.

It can be laid down as a fact that purely economic laws govern the rise and period of life and degree of usefulness of these large corporations. Purely economic laws govern their action. And the laws of economics grind slowly, but they grind exceeding fine. This is what history teaches from the days of Adam Smith down.

Comparisons are invidious, and it would be idle for me to draw comparisons to any great extent and, besides, a breach of confidence. But it is a matter of common knowledge that the United States Steel Corporation, by a policy of persuasion rather than of coercion, in 1906 and the first part of 1907 did restrain steel prices from going to extravagant high levels, and in the last three months of 1907 did hold prices from going to the everlasting bow-wows. In 1908 the prices were allowed to subside gradually, but the retreat was an orderly one, so that to-day of all the metal markets the iron and steel market is alone in a healthy and stable condition

The copper market in 1907 was a runaway one Consumers were in a panic and lake copper sold as high as 27 cents. This was due, first of all, to natural causes, such as shortage of coal and labor in the mining centers, but, second, to a more or less concerted action on the part of the producers by exaggerating actual conditions So the copper producers danced and have been paying the piper for the past year. Undoubtedly there was no actual conspiracy on the part of the producers, but action may be concerted, though entirely tacit and even unconscious

But the steel business was managed intelligently for the interests of the entire business and the copper business was handled in a spirit of narrow selfishness We see that this was a boomerang

And if the Supreme Court of the United States construes the Sherman law so that the policy of keeping prices stable and reasonable is a crime, my great respect for that body will be lessened.

It is thus seen that the policy of a trust should be to conserve the best interests of the trade and that its own interests are so best served. Stable markets are better for the consumer than unstable markets, even when the average price of the latter is somewhat lower than the average price of the former.

The trusts can act efficiently in other ways. For example, unprofitable plants can be shut down. The highest salaries can be paid to business and technical talent. General expenses or the amount paid for intelligence and diffusing it, can be large absolutely and still be a small percentage of the total cost of production. Purchases can be made in large volume, and hence low. Plants can be remodeled and new processes put in, as for example, the Héroult electric steel furnace by the Steel Corporation, and undoubtedly this is the line where commercial inertia inhibits progression. Laborers can be given steady employment, and hence are much more efficient Profit-sharing makes them partners in the concern. Money can be borrowed much more cheaply and in large amounts.

Two large trusts are typical and illustrative by reason of the peculiar nature of their business of the general excellence that trusts can have. These are Swift & Company, "the meat trust," and the United Fruit Company, the "banana trust." The former does a business of $300,000,000, in round figures, per year on a 3 per cent margin. The latter makes a marginal profit of 10 cents per bunch containing over 150 bananas. Let any business man deny that these margins are excessive. The retail margin of the small butcher and Italian who peddles bananas is from 6 to 10 times the margin of the large wholesaler. Only on one assumption can these two concerns be harmful to the body economic, and that is that the officials are stealing flagrantly from the stockholders and falsifying the books. The high personal standard of honor among the directors of these two companies precludes this idea and dismisses the assumption as absurd.

For my own part I cannot but admit that (1) the badly managed trust goes to the wall quickly; (2) the well-managed trust helps everyone but those who have become suddenly rich by its incorporation and spend all their money and all their time in riotous living. For the idle and inefficient, who lose their jobs or their property by its competition, have at least the solace of kicking, and in their own minds attributing their misfortunes to the machinations of others. They are, indeed, then happy in their misery.

Finally, let me state that Mr. Cockran's argument before the Supreme Court is that any company which has increased its production and kept its prices from advancing while general prices have advanced is not restricting trade. For increase of production is increase of trade. Nor is restriction of intelligent competition restriction of trade. In short, restraint of trade is one thing and restrain of competition is another thing. Mr Cockran further points out that if trade is restrained by conspiracy or acts of violence it is certainly against the common law of our country and England, and, hence, punishable by fine or imprisonment.

In short, Judge Parker was right in 1904 when he said that the trust question could be solved by the application of common law Possibly ex-President Roosevelt was also right in his solemn affirmation that a good trust is good for the country and that a bad trust is bad for the country. But in the modern schools of psychology the theory of value is prevalent, and to evaluate the good in men, women and things is an eternal problem. It were far better for the American people to stick to the common law, not to try to legislate morals into themselves, and ever to seek to evaluate the things as they see them in the light of things as they are

Temperature Conversion Table.

Through the courtesy of Dr. Leonard Waldo, consulting engineer, of 49 Wall Street, New York City, we are enabled to reproduce herewith his very convenient Centigrade and Fahrenheit temperature conversion table.

Dr. Waldo's table is self-explanatory. It will be found to be based on an arrangement well known from logarithmic tables, but novel for the conversion of temperatures. Besides convenience it has the advantage of exactness, i. e., the values of temperature found from the table are exact, not approximate.

Advantages of Enriched Air Blast.

By Jos. W. Richards.

If we consider what effect air enriched in oxygen can have upon the working of a blast furnace, the first and immediate effect will undoubtedly be the increase in maximum available temperature before the tuyeres. What that will be can be calculated with exactness for air of any given percentage of oxygen.

The next question is, what effect this increased temperature will have upon the running of the furnace. Here calculation cannot be made with exactness, and only general observations can be made as to the effects which these high temperatures will produce.

The normal percentage of oxygen in pure air by volume is 20.8, nitrogen (argon, etc.) 79.2. For the purpose of discussing the effect of enriching the air in oxygen, upon the working of a blast furnace, we can leave out of consideration the presence of water vapor in the blast, or of the small amount of CO^2 in the air, and confine our attention to the oxygen and accompanying nitrogen.

Using cold pure air in the blast furnace, the combustion of the carbon being practically entirely to carbon monoxide, CO, the theoretical maximum combustion temperature attained is 1678° C. (Metallurgical Calculations, Part II, p. 282). If the air is preheated to 1000° C., the theoretical maximum is 2520° C., an increase of 842° C., or 84° for every 100° heat in the hot blast.

The function of hot blast is to increase the total amount of heat available per unit of carbon burnt before the tuyeres. This increase in available calories results in raising the temperature of the furnace gases in the smelting zone without changing their quantity, and thus renders available for smelting down purposes a larger quantity of heat units per unit of carbon burnt, at a *higher* initial combustion temperature. The net results are that the unit of carbon burnt before the tuyeres smelts down more iron and slag and smelts quicker, because of the higher initial combustion temperature. This produces less CO before the tuyeres per unit of iron smelted, resulting in a better production of CO^2 above the tuyeres, and therefore better utilization of carbon as a whole in the furnace.

The weak spot of the blast furnace is the smelting zone, and any factor which increases the amount of available heat units in that zone, and their initial combustion temperature, works great economy in the furnace.

More or less dried blast works similar results for a similar reason. The removal of moisture increases the available heat units in the smelting zone by the heat previously necessary to decompose the moisture. This results in more heat units available, and at a higher initial combustion temperature. Irregularities of temperature due to changes in the weather are also eliminated, making for more regular running, and saving the margin of excess fuel usually carried against such emergencies as a rapid increase in air humidity.

More available heat units in the smelting zone at a higher initial combustion temperature is the secret of the efficiency of hot blast and of dried blast.

It is possible to still further increase these two factors of economy. By increasing the percentage of oxygen in the air we *do not* increase the heat units available per unit of carbon burnt, but we increase, for the same available heat units, their initial combustion temperature. Operating with a blast of air preheated to 500° C., let us say, pure air gives a theoretical maximum combustion temperature of 2096° C. This is not the temperature to which the materials being smelted are raised, but is the initial temperature of the gaseous products of combustion at the moment of their formation, which products by cooling down impart their heat to the materials being smelted.

If, now, the air used is increased, say, 5 per cent in oxygen, to 25.8 per cent oxygen and 74.2 per cent nitrogen, the amount of inert nitrogen carried in is decreased 24 per cent for a given quantity of oxygen and it can be calculated that the maximum temperature of combustion will be increased to 2466°, an increase of 370°. It should be noted, however, that this increase of temperature is not accompanied by any increase in the number of available heat units per unit of coke burnt; these remain unchanged, but they are available at a much higher initial temperature.

We must next show what effect this higher initial temperature of the same number of heat units can have on the furnace running. It effects the rate of transfer of heat to the substances being smelted, i. e., the rate of smelting down. The gases produced are 16 per cent smaller in volume and at nearly 18 per cent higher temperature. They will, therefore, cool off in giving up their sensible heat to the materials being smelted very much faster; how much faster is somewhat problematical. As an estimate, we could say that the smelting operation might proceed 16 plus 18, or 34 per cent faster. This would mean an increased capacity of the furnace of one-third.

Faster running would further decrease radiation losses per unit of iron made; smaller volume of nitrogen would decrease the velocity of the gases through the charge and therefore increase the efficiency of reduction, i. e., the percentage of CO^2 in the escaping gases, the temperature of the escaping gases would also be decreased, more of their heat being thus left in the furnace. The temperature of the furnace would decrease more rapidly above the tuyeres than it now does, giving a lower average temperature to the outside furnace shell and therefore decreased radiation and conduction losses to the air. The escaping gases would be relatively richer in combustible, and therefore better fuel gas.

Summarizing these advantages, we feel confident in predicting that when a blast furnace is run on air enriched 5 per cent in oxygen, that it will run normally one-third faster than when run with ordinary air, and will save probably one-sixth the fuel requirement.

Lehigh University.

The Silver Cyanide Mill of the San Rafael y Anexas Co., Pachuca.*

By E. Girault, *General Manager.*

This mill, built in 1908, belongs to the type introduced the year before in the San Francisco Hacienda by Mr. A. Grothe, to whose foresight and personal effort we owe the most efficient

Fig. 1.—General view of the cyanide mills of the San Rafael y Anexas Company, Pachuca.

and rapid cyanide process known in Mexico, and to whom credit must be given for the valuable service thus rendered to the silver industry of Mexico.

Ores.—The ores from the San Rafael Mines, derived from the Vizcaina vein (the mother lode of the district), contain from 70 per cent to 75 per cent silica and from 10 per cent to 20 per cent of limestone. The silver, mixed with a small amount of base sulphides, is found mostly in the state of Ag_2S. The gold occurs in a nearly constant proportion of 4 grams to 5 grams per kilogram of silver in the low, and 3 to 4 in the high grade ores.

All ores above 300 grams of silver to the ton are cyanided.

Treatment.—The ore is hand-picked; crushed in Blake crushers and sampled in the mine yard; ground in cyanide solution in stamp batteries; concentrated on Wilfley tables; classified in Dorr classifiers; reground in Krupp tube mills; settled in Dorr pulp thickeners, and agitated in Pachuca pneumatic tanks.

The solutions are filtered in Moore vacuum filters and precipitated on zinc shavings.

Plans I and II show the flow through the mill.

Power and Water Supply.—The mill is driven by electric power supplied by the "Compania de Potencia de Regla" Westinghouse motors being employed.

Each battery of 20 stamps has a 75-hp motor; each Krupp mill one of 100 hp.

The total power consumption is 1.68 hp-day per ton of ore.

The water supply is drawn from the mine; the water is slightly alkaline.

Crushing.—There are 80 stamps in use; 40 Krupp, of 850 lb., set on timber foundations, and 40 Allis-Chalmers, of 1250

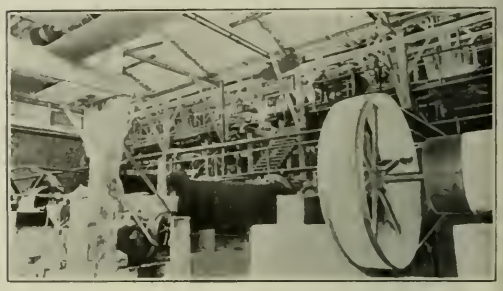

Fig. 2.—Inside view of mill.

lb., bolted to concrete foundations. The light stamps drop 7¾ in. and the heavy ones 6¾ in. 104 times per minute. The shoes and dies of forged steel last from 90 to 100 days.

Tyler's ton-cap screens, Nos. 58 and 365, equivalent to No. 10 mesh, 18- wire, 1.32 mm opening, and to No. 12 mesh, 20-wire, 1.067 mm, respectively, are used in the batteries.

The 850-lb. stamps crush from 3 tons to 3½ tons through 10-mesh per day; the 1250-lb. stamps crush from 6 tons to 6½ tons through 10-mesh, and from 5½ tons to 6 tons through 12-mesh per day.

From 7 tons to 8 tons of solution of one of ore is used in the batteries.

With No. 10 screens the capacity of the batteries is 400 tons per day, but at present crushing is limited to 350 tons to avoid overloading of the tube mills.

One pair of spring rolls, 36 in. x 16 in., and two more tube mills have been ordered; when installed No. 8 screens will be used in the batteries, and it is expected to raise the crushing to about 500 tons per day.

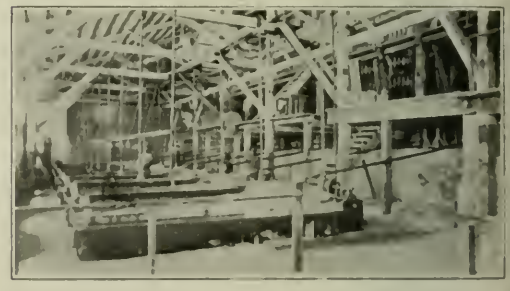

Fig. 3.—Concentration plant.

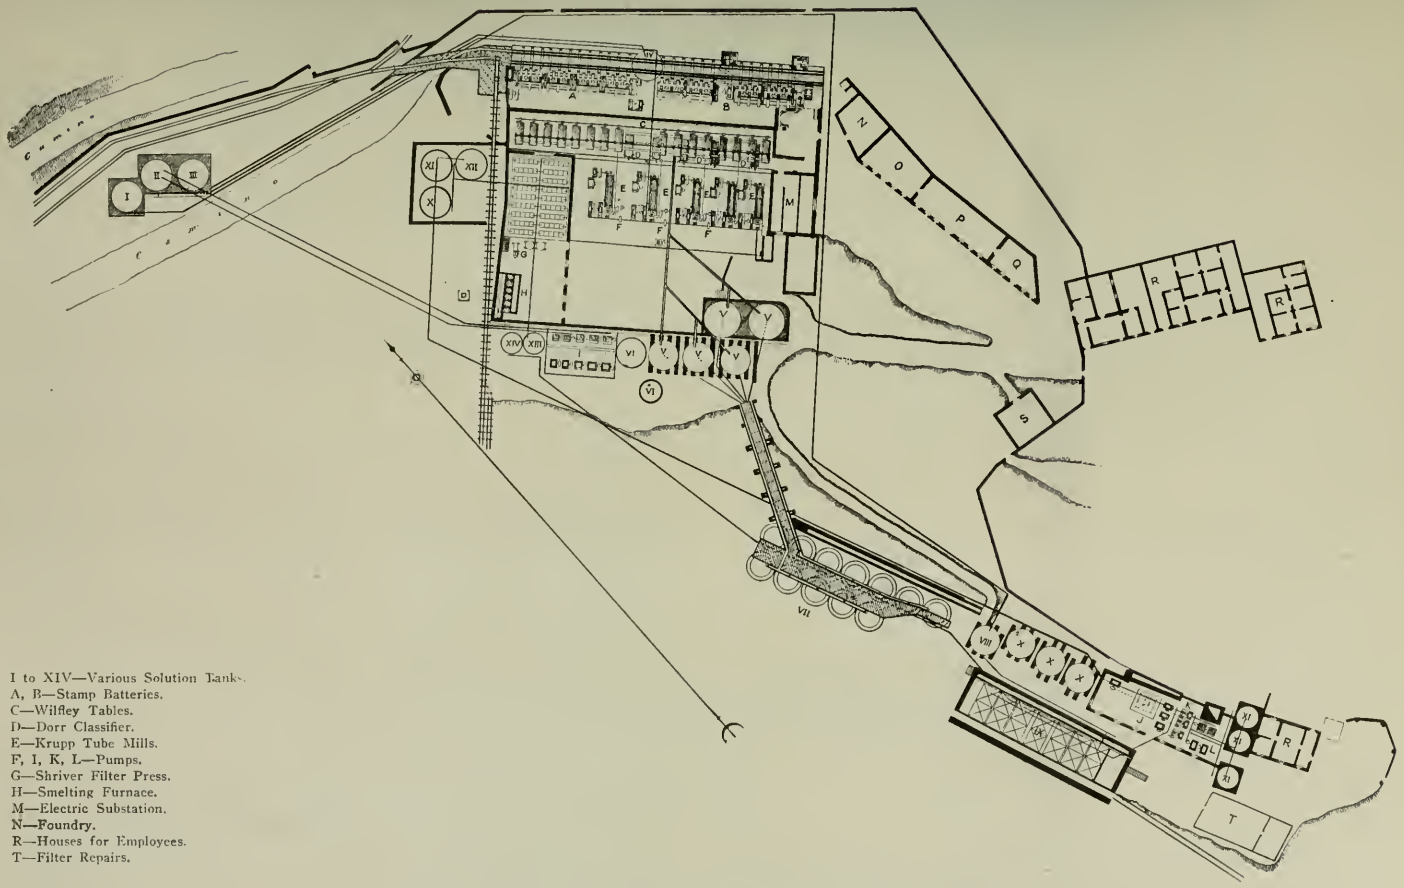
The following is a sizing test of the battery pulp, No. 58 ton-cap — No. 10 mesh screens being used.

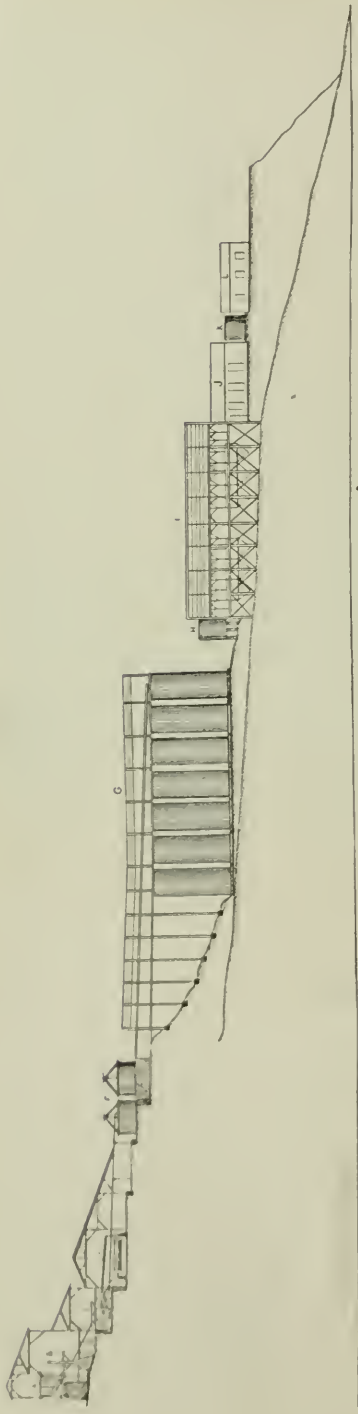
+ 40	37	per cent
+ 60	9	" "
+ 100	7	" "
+ 150	13	" "
+ 200	4	" "
— 200	30	" "

The total power consumption in grinding, including crushers, stamps and tube mills, is 1.05 hp per day per ton.

*A paper presented before the Instituto Mexicano de Minas y Metalurgia. From Informes y Memorias del Instituto vol. I, No. 3. Dec., 1909.



PLAN OF CYANIDE PLANT, SAN RAFAEL, PACHUCA, MEXICO.



CYANIDE PLANT, SAN RAFAEL, PACHUCA.

B—Stamps. C—Wilfley Tables. D—Dorr Classifiers. E. Krupp Tube Mills. F—Dorr Pulp Thickeners. G—Pachuca Tanks. I—Moore Filter. J—Compressor and Pumps. K—Rich Solution Tank. L—Houses for Employees.

Mill Solution.—This is stored in two tanks, II and III, of 200 cu. m. each; these tanks are used alternately to supply the mill and to receive the barren solution, being worked in cycles in order to avoid the enrichment of the solution.

According to the class of ore treated from 6 kg to 12 kg of

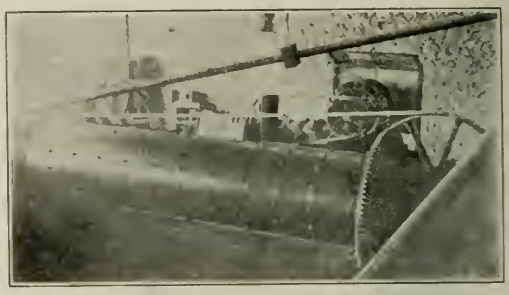


FIG. 4.—TUBE MILL.

lime are added in the bins per ton of ore. The alkalinity of the solutions is kept at 1 kg of CaO to the ton.

The mill solution averages 0.25 per cent of KCy; the cyanide loss in crushing is about 600 grams to the ton of ore. The extraction in the grinding process is high, averaging during October 38.3 per cent of the silver and 70 per cent of the gold contained in the ore.

Concentration.—Sixteen Wilfley tables, one for each five stamp battery, are used.

FIG. 5.—PACHUCA TANKS

From 17 tons to 30 tons of ore per day are fed to each Wilfley without overloading them.

The Wilfley tables are also used for unwatering the pulp and as auxiliary classifiers; the slime overflow being sent to pulp thickeners.

During the month of October 22.09 per cent of the values were recovered in concentrates containing:

Silver	25.586	kg per ton.
Gold	126	gr. per ton.
Iron	34.45	per cent.
Silica	12.25	" "
Lime	3.40	" "
Sulphur	40.50	" "

The concentrates were sold to the smelters.

Classification.—Five Dorr classifiers, one for each tube mill, are used.

From 50 tons to 70 tons of pulp, all the return from the tube mill, are fed to each classifier, the pulp being in the proportion

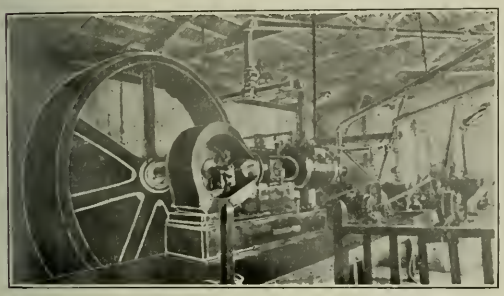

FIG. 6.—AIR COMPRESSOR.

of 1 to 2.38 of solution; the discharge contains 1 of solution to 2 of dry sand.

The Dorr classifiers have been working continuously for one year without giving any trouble.

The slime discharge classified averaged in October:

+ 100	2.5	per cent.
+ 150	15.5	" "
+ 200	7.5	" "
— 200	74.5	" "

Tube Mills.—Five Krupp No. 5 tube mills, 4 ft. x 20 ft., with Neal's baffle at both ends and El Oro liners, are in use.

Their capacity is rated at 50 tons of sand per day, the heads averaging:

+ 100	48.0	per cent.
+ 150	39.6	" "
+ 200	4.2	" "
— 200	8.2	" "

The tails, 74.5 per cent — 200, as noted above under classification.

Pulp Thickeners.—Five Dorr pulp thickeners, receiving slime diluted 1 to 10 and discharging 1 of dry slime to 1.2 of solution, are employed to unwater the pulp previous to agitation in the Pachuca tanks.

Three of the thickeners, 20 ft. x 10 ft., are supplied with 70 tons of dry pulp each; the other two, 24 ft. x 10 ft., will take 100 tons per day, and all overflow clear solution.

Pachuca Tanks.—Ten 15-ft. x 45-ft. Pachuca tanks are used for the agitation of the pulp at present; two more have been ordered and are soon expected.

The average charge is 100 tons of dry slime and 120 tons of solution.

One part of slime to one of solution (120 tons of slime to 120 of solution) has been tried, as well as 1 to 2, and 1 to 3 solution, but the best proportion was found to be 1 of ore to 1.2 of solution.

Compressor.—One Rand-Ingersoll air compressor, 18¼ in. diameter by 16 in. stroke, delivering at 100 revolutions 700 cu. ft. of air per minute to elevation, is employed for supplying air to the Pachuca tanks, to the Moore filter tanks, etc.

The amount of air required for an energetic agitation in the Pachuca tanks is estimated in San Rafael at 100 cu. ft. per minute at 25 lb. pressure.

The pulp is agitated during 36 hours, as it has been found that during this period the silver extraction increases about 20 gr.

Filtration.—Two units of the type A No. 3 of the Moore filter are employed; a third unit has been ordered.

The leaves are 10 ft. x 6 ft., and their capacity is 2.5 tons of dry slimes per day; 160 leaves in four baskets of 40 each are used, and 80 more are kept in reserve for repairs.

Two traveling cranes. worm-geared with 30 hp for traveling, are used for transferring the baskets.

According to the condition of the leaves a 1-in. cake is formed in from 20 minutes to 30 minutes.

One hour barren solution wash, and 15 minutes water wash are given to the cakes.

On each basket one 16-in. x 20-in. spiral pipe serves as vacuum chamber and holds the cake during the five minutes of the transfer.

In order to clarify the solutions, sand filters are used before the zinc boxes.

During October the water discharge assayed 4.5 gr. of silver to the ton; the cake, 55 grams unwashed and 50 grams washed.

During November, treating higher-grade ores and employing three baskets only, one of them in bad state, the cake discharged assayed 71 grams of silver unwashed and 63 grams washed.

Precipitation.—Zinc shavings, 0.006 in. thick, are used in precipitation.

Two tons of solution to the ton of ore are precipitated.

The heads in the boxes assay from 200 grams to 300 grams of silver; the tails, 2 grams.

The clean-up is made weekly.

The short zinc, which remains on a 20-mesh screen, is returned to the boxes; the shorts on 40-mesh are melted.

The precipitates are pressed and dried to 20 per cent moisture on a 24-in. x 24-in. Shriver press.

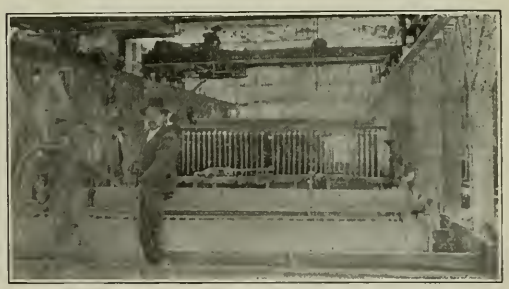

FIG. 7.—MOORE FILTER PRESS.

Melting.—Coke furnaces and Dixon's No. 300 graphite crucibles are employed.

The precipitate is melted with the following flux:

15 per cent broken glass.
6 per cent borax.
4 per cent sodium carbonate.

The short zinc, which remains on the 40-mesh screen, is fused with:

20 per cent broken glass.
8 per cent borax.
6 per cent sodium carbonate.

The bars, without remelting, assay from 920 gr. to 950 gr. silver and 5 gr. of gold to the kilogram of silver.

The slags are crushed quarterly in a battery and concentrated on a Wilfley table. The concentrates are melted and the tails treated in the cyanide plant or sold.

Resume.

The resume of the November, 1909, results is given below:

Tons crushed, 8393.

Assays per ton of ore:

Ore Contents:

Silver	0.901 kg	(28.967 oz. troy).
Gold	4.430 gr	(0.151 oz. troy).

Concentrates:

Silver	25.348 kg	(814.938 oz. troy).
Gold	141.600 gr	(4.552 oz. troy).

Heads of Pachuca tanks:

Silver	0.397 kg	(12.763 oz. troy).

Filter discharge:

Unwashed silver	0.071 kg	(2.283 oz. troy).
Washed silver	0.063 kg	(2.025 oz. troy).

FIG. 8.—PRECIPITATION BY ZINC SHAVINGS.

Extraction:

In concentration, silver	24.19 per cent.

Cyaniding:

Crushing	31.74 per cent.
Agitation	36.18 " "
Total extraction, by assays, silver	92.11 " "
Total extraction, by calculation, silver	91.43 " "
Total extraction, by calculation, gold	97.08 " "

Consumption per ton of ore:

Sodium cyanide, 128 per cent	1.078 kg.
Lead acetate	0.317 "
Lime	6.706 "
Flint pebbles	1.227 "
Zinc	0.843 "
Coke	1.646 "
Borax	0.084 "
Soda carbonate	0.044 "

The cost per ton was:

General expenses	$0.78
Grinding and concentrating	1.18
Cyaniding	1.32
Pumps and compressor	0.15
Filtration, including royalty	0.33
Precipitation and melting	0.44
Total Mexican money	$4.20

Properties and Behavior of Furnace Electrodes.

By Carl Hering.

In an article in the October issue of this journal (Vol. VIII, p. 442, 1909) the writer described an analysis of the laws of the proper proportions of electrodes and the losses of energy in them, based on the fundamental principle that there should be no chilling of the furnace by the electrodes or unnecessary heating within the walls. Owing to the great mathematical complications involved by including in the algebraic deductions some of the refinements which belong more properly to what is termed the second approximation in a complicated case, the writer preferred the method more generally used in such cases and recommended by our ablest scientists, to take up the simpler case first by itself, and consider the refinements later in the form of corrections. He then showed how most of these corrections could readily be taken care of by determining the physical constants in such a way as to include those factors, thus making the simple solution practically exact.

In any case, no matter how complicated, and as far as it concerns the electrode as a whole, that is, the end results only, an electrode may always be considered to be replaced by another whose conductivities are uniform throughout and equal to the mean, virtual or average conductivities of the original one; this equivalent electrode then follows the simple laws developed by the writer. The end results, that is, the flows of heat at the two ends, will be the same in the equivalent electrode as they are in the original, but the behavior of the parts intermediate between the ends will not.

The whole subject is discussed more in detail, accompanied by experimental determinations, tables and curves, in a paper on "The Proportioning of Electrodes for Furnaces" to be read before the American Institute of Electrical Engineers and to be published in the *Proceedings* of that society for March.

Although the problem of calculating electrodes so as to include these corrections is thereby solved in a very simple way, it is nevertheless quite instructive and of interest to examine what the nature of the changes in the behavior of the intermediate parts of the electrodes are, which are caused by the different physical properties of the materials, including the temperature variations in the conductivities. The purpose of the present article is to do this.

When a mathematical analysis becomes so complicated that it confuses and obscures rather than clarifies the situation, one may often obtain very useful results by means of analogies. In the present article the effect of those changes will be examined in this way.

The comparisons will be made between a flow of electricity (an electric current), a flow of water, and a flow of heat.

Analogies.—In Fig. 1 let E be a very large electrically charged sphere whose potential above the earth is E. Let the conditions be that a wire R of a uniform resistance must be attached to it and to the earth; a current C would then flow whose value is $C = E/R$, supposing the charge to be practically infinite, and R to be the resistance through which the current passes. This current is a flow of coulombs per second. Let it be required to stop this flow without opening the circuit. This can evidently be done by passing a current equal to C from some other source into the wire at the extreme end a near the sphere. Or it may be done by a current equal to $2C$ applied at the middle point b; or by a current $10C$ applied at a point c, which is 9/10 of the whole distance from the sphere.

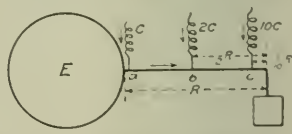

FIG. 1.— ELECTRICAL ANALOGY.

It will be seen that the current which is required increases in the same proportion as the point of application is moved nearer the zero end. In all cases E is always the same, and C increases as fast as R diminishes, so that their product is always equal to E. But the power required is $C\,E$, hence it will increase in proportion to C—that is, it will require the least power when the current is applied at a, and most when applied at c.

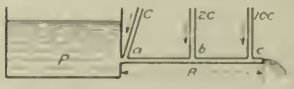

FIG. 2.—ANALOGY WITH FLOW OF WATER.

It will be noticed that when the current is applied at the

middle point *b*, it amounts to the same thing as a current entering the wire all over its whole length, at a uniform rate per inch. Or in other words, the points *a*, *b* and *c* may be considered to be the centers of gravity of currents entering all over the wire, evenly for the point *b*, and unevenly for the points *a* and *c*. If for any other distribution of the entering current the center of gravity of the distribution is known, the above laws may be applied.

In Fig. 2 let *P* be a tank of water with a pipe *R* attached to it having a resistance to the flow; and assume for the sake of the analogy, that this resistance also follows a law like Ohm's law. Then exactly the same argument applies to stopping the outflow of water from this tank dynamically by streams of water entering the pipe at various points *a*, *b* and *c*, or all over, either regularly or irregularly, the center of gravity of such distributed influx being known.

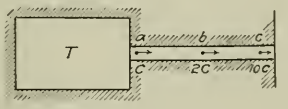

FIG. 3.—FLOW OF HEAT IN ELECTRODE.

In this case it is the hydraulic pressure *P* of the tank which is always the same, and the various currents *C*, now the current or flow in gallons per second, must always be such that $C = P/R$. The current and the power to produce it will again increase in proportion as the center of gravity of its application moves away from the tank.

In Fig. 3 let *T* be a furnace having a constant temperature *T*, and let *R* be an electrode offering a resistance to the flow of heat, and having its other end kept cold. The analogy applies again. The flow of heat *C* from the furnace is again such that $C = T/R$, the temperature *T* being now that quantity which is always the same. This flow can again be stopped by the application of another flow in the same direction from an independent source. If the resistance again follows Ohm's law, as it does, the same conclusions apply as those found above, namely, that the flow of this applied heat will be least when applied near the furnace end, and will increase as the center of gravity of its application is farther from the furnace. The flow or current is now measured in calories per second, which is a quantity of the same nature as watts. In this case the heat current itself is power, hence the flow or current and the power to produce it are numerically the same.

The number of watts required to stop the flow from the furnace will therefore increase in the proportion as the center of gravity of the inflow from the other source is farther removed from the furnace. It will be greater or less than $2C$, depending upon whether the center of gravity of its point of application is to the right or left of the middle point *b*, respectively.

Now, this inflow of watts may be produced by an electric current in the electrode *R* itself, as it actually is done in practice. The rate of production of these watts along the electrode will then depend upon the local resistance—that is, the electrical resistivity at the various places. If it is evenly distributed—that is, if the resistivity is constant for all temperatures, it will be equivalent to all the watts being generated at the middle point *b*. In that case, from the analogy, the power required will be twice that represented by the watts of heat flow from the furnace if there were no additional current. This is the case assumed by the writer in the analysis referred to above.

Varying Electrical Resistivity.—Now let it be assumed first that the thermal conductivity is constant throughout, and that the electrical resistivity falls with the temperature, as it does with carbon. Then it is evident that more watts will be generated in the colder half than in the hotter one. Hence, the center of gravity for the whole length will be moved toward the colder side of the middle; hence, the conditions will approach to those in Fig. 3, in which the watts are applied at *c* near the cold end. From the analogy it follows that the watts now required to stop the furnace flow will be *greater* than they were for an electrode having the same total resistance but evenly distributed. And they will become greater the faster the resistivity falls with the temperature. As these watts are the electrode loss, it follows that *a falling resistivity increases the loss*, because it moves the center of gravity of the generation of the watts toward the cold end.

Hence, a falling resistivity is an undesirable feature for an electrode. In unscientific terms, it may be said that it crowds the heat toward the cold end where it is not wanted. In Fig. 4, if *b* is the normal heat gradient for a constant resistivity, then a falling resistivity will tend to give it a shape more like the curve *c*, which is undesirable.

Let it now be assumed that the resistivity rises with the temperature, as it does with iron. In an iron electrode more watts will be generated in the hotter than in the colder half. This moves the center of gravity of the total watts toward the hot end; hence, the conditions will approaoch those in Fig. 3, in which the watts are applied at *a* near the hot end. It has been shown that the watts required to stop the flow of furnace heat will then be *less* than when applied at the middle. Hence, in iron electrodes less watts will be required to stop the flow of furnace heat than if the resistivity were constant. And the number of watts will become less and less as the resistivity rises more rapidly with the temperature.

Hence, as these watts are the electrode loss, it follows that *a rising resistivity diminishes the loss*, and is therefore a desirable feature in an electrode. It may be said that it crowds the heat toward the hot end, which is the right place for it to be. Referring to Fig. 4, it tends to change the normal heat gradient from *b* toward *a*, which is very desirable; the more rapidly this curve falls at the hot end and the less rapidly at the cold, the better.

Varying Thermal Conductivity.—Now let it be assumed that the electrical resistivity is constant and that the thermal conductivity varies with the temperature. The watts will then be generated evenly throughout the whole length.

When the thermal conductivity falls with the temperature it means that the heat gradient will fall more rapidly in the hot half and less rapidly in the colder half than it would for a constant conductivity. Referring to Fig. 4, it will tend to change the heat gradient from *b* to *a*. This, as was pointed out above, is in the right direction. Hence, *a falling thermal conductivity is a desirable feature.*

When, on the other hand, the thermal conductivity rises, it means that the heat gradient will fall less rapidly in the hotter half and more rapidly in the colder one than for constant conductivities. Referring to Fig. 4, this will tend to change the normal gradient *b* to the undesirable one *c*. Hence, *a rising thermal conductivity is an undesirable feature.*

Examples.—Recent determinations of these physical constants by the writer show that up to about 1000° C., and probably above that also, carbon has a falling electrical resistivity, and a rising thermal conductivity (not a falling one, as has been incorrectly claimed.) Hence, in this material both features are in the undesirable direction, as they both tend to crowd the higher temperatures toward the colder end, where they are not wanted; and as was shown above, this increases the minimum loss. As both these tendencies are in the same direction, each in turn helps to increase the other, making the final heat gradient worse than it was for either alone. The heat gradient for a carbon electrode will therefore be somewhat like the curve *c* in Fig. 4.

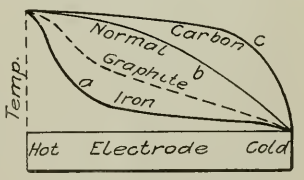

FIG. 4.—TEMPERATURE GRADIENTS.

On the other hand, these same determinations have shown that for iron the electrical resistivity rises rapidly and the

thermal conductivity falls. Hence, both are in the favorable direction, as they both tend to crowd the higher temperatures back toward the furnace where they belong; and this tends to reduce the minimum loss. Again, as both features act in the same direction, each in turn will increase the other, making the final heat gradient better than it would be for either alone. The heat gradient for an iron electrode will therefore be somewhat like the curve *a* in Fig. 4.

For graphite these tests showed that the electrical resistivity falls, though much less rapidly than for carbon, at least for moderate temperatures; it is, in fact, not very different from a straight line. Graphite, therefore, shares this undesirable feature with carbon, though it possesses it to a less degree. But, on the other hand, the tests showed that the thermal conductivity falls, and quite rapidly, much more rapidly than for iron. Hence, it shares this good quality with iron. As these two features are now opposed to each other in their action on the heat distribution in an electrode, they tend to neutralize each other; but as the rate for the falling thermal conductivity is considerably greater than that for the rising electrical resistivity it predominates, the result being that it moves the heat gradient below the normal one *b*, Fig. 4—that is, toward the one for iron, *a*, which is the favorable direction. Hence, graphite, like iron and unlike carbon, tends to crowd the heat toward the hot end where it belongs.

This feature was also confirmed by a comparison of the resistivities of graphite *at* various temperatures with those obtained by the writer, which are the mean values for various ranges of temperatures. The rate of change of the latter was found to be less than that obtained by the arithmetic means of the former, as it should be.

Thermal Insulation.—Incidentally, the different shapes of the heat gradients in Fig. 4 indicate the error that would be committed by assuming any fixed coefficient for the leakage of heat from the electrode to the walls, as has been suggested. This leakage, however little or much it may be, depends, of course, on the differences between the temperatures of the electrode and of the wall at neighboring points. Now, the heat gradient in the wall will presumably be approximately a straight line joining the two ends of the heat gradient curves in Fig. 4. Hence, for carbon the leakage would be from the electrode to the wall, while for iron and probably graphite, too, it would be from the wall to the electrode; hence, not only different in values and in place, but even with a reversed sign! This shows the great mistake that might be made by measuring such a coefficient for carbon, for instance, and then applying it to an iron or graphite electrode; it would make matters worse than to let it alone.

Electrode Means.—The empirical values above referred to are the proper mean values to be used in the formulas developed by the writer and given in the earlier paper above referred to. They are the values of an equivalent electrode whose two conductivities are constant throughout the whole length of electrode and are equal to this value for each particular range of temperature, but have a different constant value for a different range. Such an electrode *as a whole* will act just like the original one, differing only in the distribution of the heat between the ends—that is, in the heat gradient, as was discussed in this article. As these values are a mean peculiar to electrode conditions, being neither exactly an arithmetic or geometric mean, the writer proposes to designate them by the term "electrode mean."

It may be of interest to add here that when these electrode mean values are used all the laws of electrode losses deduced by the writer in his former article seem to apply correctly even when the variations of the conductivities with temperature are very great. The explanation seems to be that these experimentally determined mean values embody all the correction factors due to these variations.

The results of these experimental determinations are in part surprising, as they show that some of our former figures have been considerably in error, in one case even in the direction (sign) of the variation. This is in part due to the fact that they are the electrode means and therefore include the effects of the variations pointed out in this article.

Carbon turns out to have a much higher mean thermal conductivity than was formerly supposed, bringing it up to about half that of graphite instead of 1/8 and 1/10, as has been claimed. This high mean value is undoubtedly due in part to the properties described in this article. For graphite it is also higher, being above that for iron. These data are published elsewhere in detail, but briefly it may be said here as a confirmation of what has been deduced in this article, that for a range of temperature of about 1400° C. to 100° C. the minimum losses are about in the following ratios: Copper, 1; iron, 1.5; graphite, 5.0, and carbon, 7.5. While as to the size, the proportions are about: Copper, 1; iron, 6.6; graphite, 14.5, and carbon, 45.

The writer's researches have, therefore, shown that in almost, if not even in all these features, the material which has been most used for electrodes, namely, carbon, is the worst, while by far the best, if it could be taken advantage of, would be copper.

Another result of the writer's investigations showed that, although the two conductivities of electrode materials are interesting, instructive and useful quantities in an investigation of this kind, and enable the behavior of the electrodes to be studied, neither of them alone are direct measures of the desirable qualities of a material for electrodes, as was clearly described in his earlier articles and papers. This led to finding what physical properties are the true relative and absolute measures of the desirable qualities of materials when used for electrodes, and this, in turn, shows that when these latter constants are determined, the two conductivities are no longer concerned and, therefore, need not even be known at all for calculating the proportions of electrodes or the losses in them. In fact, these conductivities have in the past even misled us to quite wrong deductions and conclusions, some of which have become so deep-rooted that it will be difficult to correct them. By using these new and more rational physical properties, and deductions from them, the extreme simplicity of the calculations brings them almost into the same class as those based on Ohm's, Faraday's and Joule's laws. These two new quantities are the electrode voltage and the specific section, as also their derivatives for specified temperature ranges, as explained more in detail in the paper above-referred to.

Philadelphia, Feb. 14, 1910.

Definition of Industrial Terms.

At the recent annual meeting in Boston of the Division of Industrial Chemists and Chemical Engineers of the American Chemical Society, a committee was appointed by the chairman, under authority of the by-laws of the section, "On the Definition of Industrial Terms." In constituting this committee, it is the desire of the division that it co-operate as far as possible with trade organizations in the several lines of industry in formulating definitions of their products which shall be as accurate and as fair as possible to the interests involved. The organization of such a committee has been suggested by various interests who desire a more authoritative definition of some industrial terms such as "petroleum ether," "gasoline," "benzol," "bronze," "benzine," "steel," "Portland cement," etc.

The general committee is desirous of receiving suggestions from all who are interested in the subject as to terms which are considered the most important to be defined at the present time, owing to ambiguities which may now exist, and as to the best methods of accomplishing the work. All communications should be addressed to Mr. Clifford Richardson, 30 Church Street, New York City, who is chairman of the committee, the other two members being Messrs. J. B. F. Herreshoff and George T. Adamson.

The Magnetic and Electrical Properties of Iron-Silicon Alloys.

By Charles F. Burgess and James Aston.

The belief was held for a long time that, as far as magnetic properties were concerned, purification was the method to be looked to for improvement of iron; that the highest permeabilities were to be reached the nearer our material approached an analysis of Fe 100 per cent.

That this is not true is now, of course, common knowledge. The work of Barrett and Brown, in 1901,[1] on alloy steels, made by Hadfield, gave for irons with additions of 2¼ per cent of aluminium or 2½ per cent of silicon permeabilities excelling those of pure iron; investigations of the author have shown this same effect by additions of about 2 per cent of tin or about 4 per cent of arsenic.

It is not probable that the influence of these elements, all non-magnetic, is directly, or in a strict chemical sense, the cause of the marked improvement of magnetic quality. It is more likely that the effect is due indirectly through some change in the physical structure of the iron itself. This supposition is seemingly confirmed by the influence of the heat treatment of high-purity iron. Annealing at lower temperatures

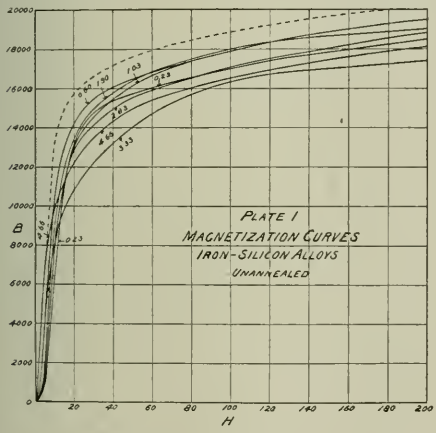

FIG. 1.—MAGNETIZATION CURVES, ALLOYS. UNANNEALED.

(about 700° C.) results in improvement of quality throughout the entire magnetization curve, due to the removal of all cooling and forging strains; while annealing at the higher temperature of 100° C. results in a deterioration of quality in the upper ranges, and a higher permeability at low magnetizing forces. And, of course, we have the concomitent increase in the grain size of the iron.

From the investigations of Hadfield, Barrett and Brown has resulted the present-day materials so largely used in transformer work, in which the percentage of silicon varies from about 3 per cent to 6 per cent. In these silicon steels the heat treatment is of importance comparable with that of the silicon content, and the practice seems to be annealing at high temperatures. The result is a material of very high permeability for the lower magnetizing forces; the saturation limit is reached at comparatively low densities, however, and beyond this point the quality is not exceptional. This characteristic makes the steel particularly suited to alternating-current working, where low working densities are the rule. The low hysteresis losses, together with the added benefits of high electrical resistance and slight deterioration due to ageing, are the special features of the silicon steels.

[1] "The Conductivity and Magnetic Properties of Alloys of Iron," W. F. Barrett and W. Brown, Jour. Inst. Elec. Engrs., Vol. 31, p. 675.

Our investigations[2] covered tests of 15 iron-silicon alloys, of which the following seven bars were analyzed and form the basis for discussion.

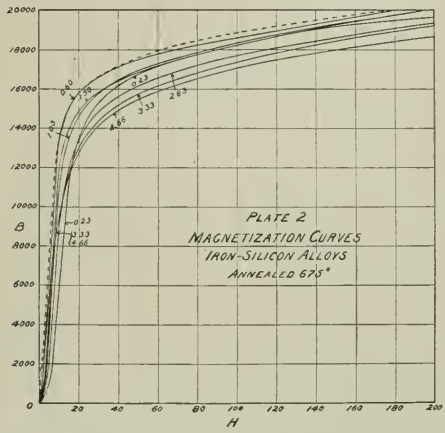

FIG. 2.—MAGNETIZATION CURVES, IRON-SILICON ALLOYS. ANNEALED 675°.

Bar.	PER CENT SILICON. Added.	Analysis.
96F	0.25	0.233
96A	0.50	0.603
96B	1.0	1.033
96C	2.0	1.897
109A	3.0	2.826
113V	7.0	3.334
96H	5.0	4.655

The agreement between added and actual silicon content is close, except for bar 113V.

As mentioned in articles which have appeared previously in this journal, electrolytic iron of high purity (99.9+) formed

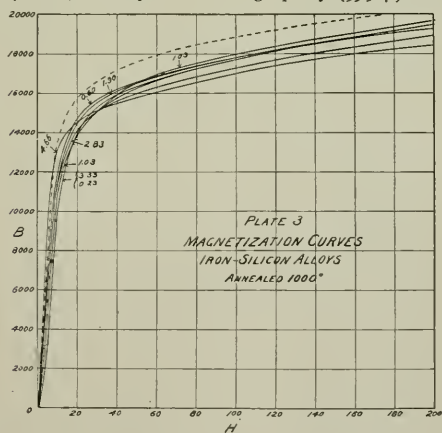

FIG. 3.—MAGNETIZATION CURVES, IRON-SILICON ALLOYS. ANNEALED 1000°.

the basis of the alloys. All effects noted, therefore, may be ascribed, as far as due to chemical composition, to the added element alone. These alloying materials were melted into ingots, which were forged and turned into bars for testing.

[2] A research on "Electrolytic Iron and Alloys" at the University of Wisconsin, under grant of the Carnegie Institution of Washington.

The results of the tests are noted in Tables I and II and in Plates 1, 2, 3, and 4. Four heat treatments were adopted—as forged, annealed at 675° C., annealed at 1000° C., and quenched at 900° C. Comparison is made with a standard bar of electrolytic iron of high magnetic quality; this is indicated in the plates by a dotted curve.

The values of retentivity given in Table II reflect the conditions indicated by the magnetization curves, and vary with the maxima reached by the curves. In general, the coercive forces become less with annealing, and reach a minimum after heating to 1000°. Quenching has had a slight tendency toward increase. The very low value of 2.7 is reached by bar 96H (Si

252	Com.			10700				13500				16400				17900	
182	Com.			11550				13850				15800				17550	

In the unannealed condition all the curves fall considerably below the standard, particularly in the upper ranges; the best results are obtained with bars of lower silicon content, and the lowest with those of highest silicon, viz., 113V, with 3.33 per cent Si, and 96H, with 4.66 per cent. However, it will be noted that for the very low values of H these two bars, and particularly 96H, cross the other curves and have the highest permeability of the series.

Annealing at 675° has raised the maxima of all curves, but the comparative order is about as in the previous condition. Bar 96A, with a low silicon percentage of 0.603, lies very close to the standard throughout the entire length.

Second annealing at the higher temperature of 1000° has resulted in a falling off of the permeability for these bars of lowest silicon content. But for three bars of highest percentage of silicon, viz., 109A (2.83 per cent, 113V (3.33 per cent) and 96H (4.66 per cent), there has been a considerable improvement of quality at the lower magnetizing forces, with but little change for the upper ranges. Here the curves fall below those of lower silicon, and all are well below the standard. The effect is most striking for bar 96H, with the highest silicon of the series

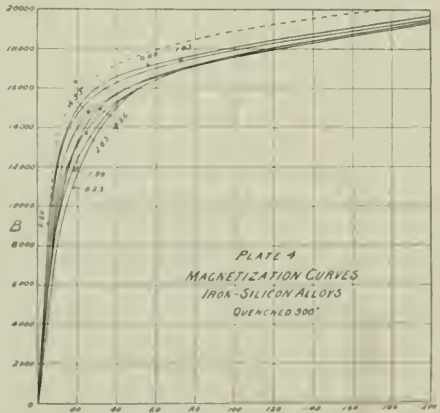

FIG. 4.—MAGNETIZATION CURVES, IRON-SILICON ALLOYS. QUENCHED 900°.

(4.66 per cent); its permeability is very high below H = 10. At this point the curve has a very sharp bend, and thereafter falls below the others. Quenching at 900° has resulted in a deterioration of quality, particularly in the lower ranges, with but little change at higher magnetizing forces

4.66 per cent) after annealing at 1000°, confirming the previous deductions of high permeability for this alloy at low magnetizing forces.

Summarizing, the results of these tests do not show a general improvement of permeability due to the presence of silicon

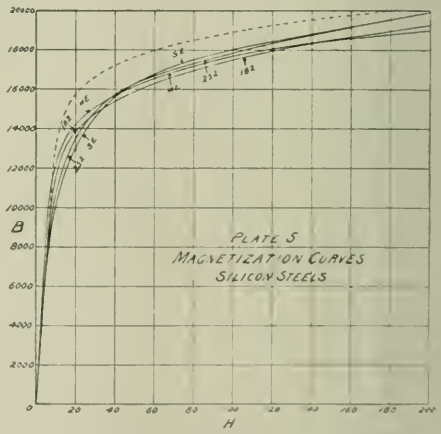

FIG. 5.—MAGNETIZATION CURVES, SILICON STEELS.

in electrolytic iron, but the experience of practice is confirmed in that a high-silicon alloy after annealing at high temperature is of high permeability for very low magnetizing forces and

densities such as are used in transformer design. The improvement is not so great in our tests as it is in commercial materials; it may be that the effect of the silicon is more pronounced in the presence of certain impurities or after special heat treatment.

Commercial Steels.

For the purpose of comparison there is appended in Tables I and II, and plotted in Plate 5, results of tests on commercial silicon steels, the samples being obtained from steel and electrical manufacturers. The tests were made upon the same apparatus as those discussed above, and the results are thus strictly comparable. The dotted curve of Plate 5 is that of the electrolytic iron standard.

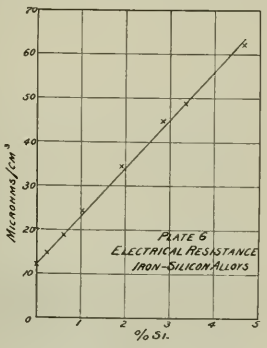

FIG. 6.—ELECTRICAL RESISTANCE IRON-SILICON ALLOYS.

The general character of the silicon steel is well shown and needs no special comment. Curves SE and 252 are of the same brand of material from a large sheet-steel manufacturer, but from samples obtained from different electrical concerns at different periods of time. The uniformity of the material is very striking; this is brought out with great clearness below, where the hysteresis tests data are tabulated.

All inductions have been carried to a maximum of B = 12,000.

Bar.	Per cent Si.	Loop area.	Relative area.	H (Max.)
117A	0	8.65	1.	8.2
96F	0.23	12.58	1.45	30.0
96A	0.60	7.05	0.81	12.5
96B	1.03	8.72	1.01	13.3
96C	1.90	9.53	1.10	1.80
109A	2.83	10.96	1.27	18.0
113V	3.33	8.77	1.02	13.4
96H	4.65	4.39	0.51	7.5
M E	Coml.	5.20	0.60	8.7
SE	Coml.	5.77	0.67	14.7
252	Coml.	6.10	0.71	14.1

These results are hardly a fair criterion of the quality of the electrolytic samples, since all were tested after quenching at 900°.

Electrical Resistance.

A feature of steels for transformer working, second only to the magnetic quality, is a high electrical resistance, to reduce the eddy-current loss. In this respect the silicon steels are an additional advantage.

Measurements of the series discussed in this paper are given in the following table:

Bar.	percent Si.	Microhms per cm³.	Relative resistance.
117A	0	12.1	1.0
96F	0.233	14.7	1.22
96A	0.603	18.7	1.55
96B	1.033	24.3	2.01
96C	1.897	34.4	2.84
109A	2.826	44.6	3.68
113V	3.334	48.6	4.02
96H	4.655	62.2	5.13
182	Coml. silicon	59.5	4.92

The above data are plotted in Plate 6, where the effect of increasing addition of silicon to the iron is indicated as an maximum of 4.65 per cent.

At this content (and this is the alloy with the minimum hysteresis loss) the resistance has risen to upward five times that of the electrolytic iron standard.

Chemical Engineering Laboratories,
University of Wisconsin.
Madison, Wis.

Manufacture and Transport of Ferrosilicon.

The British Local Government Board has issued a "Yellow Book," containing a report on the manufacture, uses, and transport of ferrosilicon. The authors are Dr. S. Monckton Copeman, F.R.S., medical inspector of the Local Government Board; Mr. Samuel R. Bennett, one of the Inspectors of Factories, and Dr. H. Wilson Hake, F.I.C., chemist.

The report was occasioned by certain accidents during the transport of ferro-silicon, which have been noted several times last year in our columns. The most interesting part of this Yellow Book, however, is probably the description of some details of operation in various European ferrosilicon works which were visited by Dr. Copeman. The chemical tests of Dr. Hake, with respect to the gases evolved, and the various researches on the properties of different ferrosilicons by Mr. Bennett and Dr. Hake also contain much of interest.

Composition of Charge.

Originally the charge of ferrosilicon furnaces was composed of a mixture of (1) iron-pyrites or other form of iron ore; (2) siliceous material in the form of quartzite or sand; (3) carbon in the form of charcoal, coal, or coke, together with (4) some lime as flux. Owing, however, to the obvious impurity (especially high phosphorus and sulphur content) of earlier samples of electric-furnace ferrosilicon, scrap-iron and steel shavings are now preferred to iron ore, and quartzite to sand, as being less productive of obstructions in the furnace. Further, the purer the starting material, the less slag will be formed. The addition of lime seems to have been entirely abandoned as unnecessary; this is of importance, in connection with the problem of the generation of dangerous gases from ferrosilicon (see below).

As the properties of the ferrosilicon produced depend to some extent on the raw materials used, the following details from Dr. Copeman's report on the raw materials used in various European plants will not be wholly without interest.

At the **Bozel** works of La Compagnie Generale d'Electrochemie de Bozel (one of the plants of the old ferrosilicon syndicate) the materials employed are as follows:

Quartz (or rather quartzite) obtained locally, containing in the average 95 per cent silicon, 4 per cent aluminium, with small amounts of calcium and phosphorus, the latter averaging from 0.3 to 0.8 per cent.

Steel turnings, containing not more than 0.3 per cent of phosphorus.

Anthracite coal, which is obtained locally and is cheap, but which yields as high a quantity as 20 per cent of ash.

The grades of ferrosilicon produced at the Bozel works represent percentages of silicon of 25, 50 and 80, respectively. In the manufacture of the 80 per cent grade, however, charcoal, although much more expensive, is employed instead of anthracite coal, on account of its great freedom from impurities.[1]

At the Keller-Leleux works at **Livet** (Isere) there are five 1200-hp Keller furnaces, making a melt of 500 kilograms of ferro-alloy every two hours, and three 500-kw furnaces, with a daily output of 12 melts, each of 2 tons. Not all these furnaces are running.

Actual working results have demonstrated that the energy required for the production of 1 ton 30 per cent ferrosilicon in the electric furnace is 3500 kilowatt hours, and at the Livet works it has been found practicable, with an expenditure of 4000 hp to turn out 20 tons 30 per cent ferrosilicon per day.

The materials employed in the Livet works in the manufacture of ferrosilicon are as follows:

Iron and steel shavings,

[1] As the cost of transport, especially in the mountain districts, constitutes an important factor, the particular form of carbon used depends on the facility with which one or the other kind is obtainable within reasonable distance from the works. In most instances anthracite coal is employed, of which large deposits are worked in the mountainous regions of the southeast of France. But this anthracite is often quite impure. Hence the substitution of charcoal in the manufacture of the higher grades of ferrosilicon.

Quartzite, containing 94 to 96 per cent silica.[2]

Anthracite coal (averaging ash 7 per cent; 0.013 per cent P., 0.4t per cent S, no arsenic).

"Iron and steel shavings, although more expensive, are exclusively used by this firm rather than 'tournures de fonte,' generally employed by other manufacturers for the reason that they contain much less phosphorus—a maximum of 0.10 as against an average phosphorus content of 0.50 to 0.80 for iron turnings."

At the **Giffre** works, St. Jeoire (Haute-Savoie), of the Société Electro-Chimique du Giffre) the constituents of the furnace consist of quartz-rock, anthracite and steel turnings, of which the quartz-rock contains about 96 per cent of silica. The anthracite of good quality from the point of view of small phosphorus content is obtained locally.

At the **Ugine** (Savoie) works of the Société Anonyme Electrometallurgique Procédés Paul Girod, the constituents of the charge are:

Quartzite, containing about 92 per cent of pure silica, with traces only of phosphorus and sulphur.

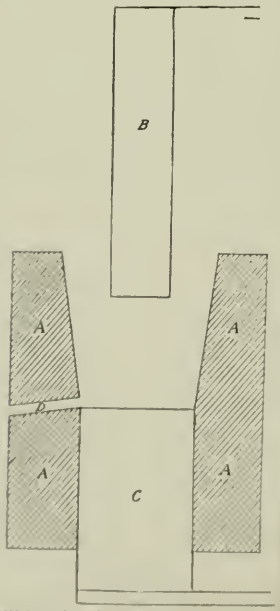
Coal (forging) obtained from St. Etienne—of best quality, and guaranteed not to average more than 8 per cent of ash, or more than .005 per cent of phosphorus or sulphur.

Steel and iron scrap.

At the **St. Marcel** (Savoie) works of the Société d'Industrie Electro-Chimiques La Volta, the charge constituents are:

Quartzite, obtained in the neighborhood of the works, with an average content of 98 per cent of silica, together with traces of magnesia, but no lime.

Gas coke, for production of the 50 per cent grade of ferro-silicon, while in the manufacture of 25 per cent alloy or other comparatively low grades this is replaced by anthracite coal, which is cheaper, but not so free from impurities.



A—Walls. BC—Electrodes. D—Tapping Hole

FIG. 1.—FERROSILICON FURNACE. DRAWN TO SCALE.

Iron-ore (for 50 per cent ferrosilicon) or steel shavings (for lower grades). The iron ore is stated to contain 95 per cent of iron oxide (Fe_2O_3), but no trace of aluminium, manganese or calcium.

The **Wednesfield** experimental station of the British Coalite Company, Ltd., use as constituents of the charge:

(1) Natural sandstone rock.

(2) Pitch, with addition of 10 per cent anthracite coal.

(3) Iron oxide.

FIG. 2.—FERROSILICON FURNACE AT GIFFRE WORKS.

The sandstone rock, utilized as the source of silica, is of a greyish color, owing to the fact that it is impregnated with about 8.5 per cent of bitumen; in addition to which it contains small quantities of other volatile constituents, including traces of nitrogenous matter. On being heated, it yields a whiteish grey, extremely friable material, small pieces of which can be readily broken down in the fingers to a fine powder, which consists of pure silica to the extent of 99 per cent.

The pitch is obtained as a by-product in the manufacture of coalite. This is used with addition of 10 per cent of its weight of anthracite coal. They would prefer to employ pitch-coke, but this from the electrical point of view would form too good a conductor.

The iron oxide consists of Fe_2O_3 precipitated in the form of a fine powder, which owing to its purplish color is useless as a paint, and so is obtainable at a much lower price than the red oxide. The average of several analyses indicates the presence of 95.4 per cent of pure iron oxide.

In making up the charge, the proper proportions of silica and iron oxide are mixed with the anthracite coal; and the whole bound together into a mass with pitch. After mixing, the volatile hydro-carbons in the pitch are driven off by heating, as the result of which the charge is left in a compact mass, which is broken up into small lumps of a suitable size for use in the furnace.

No flux is employed. The object of using pitch is the double one of ensuring that the carbon should be intimately mixed with the iron-oxide and silica, and of making the whole mass a conductor of high resistance

[2] There seems to be little difficulty in the French plants in obtaining, at a reasonable cost, quartzite or other comparatively pure form of silica, but it generally contains an appreciable amount of calcium phosphate as impurity. This is of importance in connection with the production of dangerous gases from ferro-silicon, as will be shown later on.

Furnace Construction.

Resistance furnaces are used throughout for the manufacture of ferrosilicon.

The furnaces which Dr. Copeman saw in operation at the different works visited were, for the most part, of very similar character and size, the main differences being in the external shape—usually circular (as are all internally), but in one or two instances square in section—in the size and shape of the upper electrode and in the mechanical means adopted for raising and lowering and usually for water-cooling this electrode. The furnaces at the Bozel works are provided with two tapping holes, from which the molten ferrosilicon is run alternately, whereas in the case of the furnaces at other works, one tap hole only is provided.

The furnaces are built up of fire-brick, sometimes lined with "a composition of graphite somewhat similar to that employed in the manufacture of the electrodes," and the exterior of the furnace is usually braced with iron "stays" or completely enclosed in a circular or square iron casing made up of sections bolted together.

Figs. 1, 2 and 3 show different designs of ferrosilicon furnaces. Fig. 1 is a drawing to scale of the usual type of furnace, Fig. 2 is a view of the furnace used at the Giffre works in St. Jeoire, Harte-Savoie, and Fig. 3 shows the design of the Keller furnace.

Except in the case of the furnace specially designed by Keller, of which an outline illustration is given in Fig. 3, the second lower electrode is placed beneath the floor of the furnace, its upper surface being flush with the level of the furnace hearth. At the Giffre works, for instance, this lower electrode is formed in situ by ramming into an open space in the floor of the furnace a mixture formed by heating together powdered retort graphite and coal tar.

The power employed in each furnace ranges from 250 or 300 hp to as much, in some cases, as 750 or 800 hp.

The type of furnace used in the Keller-Leleux works is such as to obviate the use of the furnace hearth as a conductor. Further to ensure the continuity of working, several electrodes are placed in parallel in the system, any one of which is renewable without the necessity of stopping or varying the working of the furnace as a whole. Keller's furnace, constructed on these principles, contains at least two groups of two electrodes each, the two latter being arranged in parallel, and the two groups themselves in series. These four electrodes of equal capacity project through refractory walls, and each electrode is provided with independent mechanism by which it can be raised or lowered at will. The intensity is equalized in each focus of the same group by means of readings taken with an ammeter, and the pressure of the group is controlled by means of two voltmeters inserted respectively between the furnace hearth and each group.

The voltage and amperage employed (the former especially) varied somewhat widely at the different establishments inspected, ranging from 40 to 75 volts, and from 10,500 to 15,000 amperes, respectively.

When once charged and started, the furnaces are run continuously for an average period of a couple of years, although, as stated at the Keller-Leleux works, the period may be extended to as much as four years. While running, the furnaces are tapped at intervals of 1 to 2 hours, the men working in shifts so that the furnaces can be attended to by night as well as by day, fresh amounts of charge being shoveled on the top of the furnace around the upper electrode as often as is rendered necessary by the melting and consequent shrinkage of the underlying mass.

Proportioning of Charge.

The charge is generally made up in proportions according to the formula

$$SiO_2 + 2C = Si + 2Co.$$

so that for every 60 parts by weight of pure silica 24 parts of pure carbon are used. But the making up of a charge is complicated by the fact that each of the three constituents, iron, quartzite and anthracite, notably the anthracite, will certainly contain impurities, the amount of which in each case has, therefore, to be determined and allowed for in the calculation.

This is illustrated by a concrete example, given by M. Barut, administrator of the Giffre Works at St. Jeoire, Haute-Savoie.

The composition of the anthracite coal in use at the time of Dr. Copeman's visit was "roughly" as follows:

Carbon ..... 82 per cent.
Ashes ..... 10 per cent.
Moisture and gases..... 8 per cent.

while analysis of the quartzite showed that it contained about 96 per cent SiO_2.

"Taking, then, the combining weights represented by the equation already referred to, viz:

$$SiO_2 + 2C = Si + 2CO$$
$$60 \quad 24 \quad 28 \quad 56$$

and noting that 24 kilograms of carbon will be represented by 30 kilograms of 80 per cent anthracite, the required proportion of silica to coal will be the simple one of 2:1, on which, however, allowance has to be made for the fact that 100 parts by

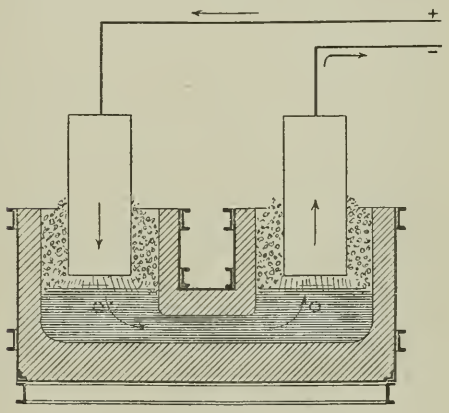


FIG. 3.—KELLER FURNACE.

weight of quartzite contain 96 parts only of silica, or about 144 kg of silica in 150 kg of quartz.

"As regards the source of the iron also, some allowance is of course necessary, seeing that the steel turnings employed will contain a certain amount of iron oxide in addition to small amounts of impurities.

"Taking these different factors into consideration, the respective weights of the several ingredients required to make up a charge for the production of, say, a 50 per cent ferrosilicon, will be as follows:

Quartz..... 150 kg (= about 144 kgms SiO_2).
Anthracite..... 72 " (= about 66 kgms Si).
Steel turnings..... 55 "

277 kg

"Dealing with these quantities:

"Sixty-six kilos silicon + 55 kilos steel turnings should theoretically yield 121 kg. all the carbon of the anthracite being given of as CO (carbon monoxide gas). But, as a matter of fact, in addition to the total disappearance of the carbon, a certain proportion of the silicon and iron (about 11 kg on the quantities here dealt with) is also not accounted for in the final product, being presumably lost through incorporation with the slag. Consequently, the amount of alloy actually obtained from the above charge of 277 kg will be 110 kg only of 50 per cent ferrosilicon.

"In the event of a lesser or greater silicon percentage being required, the weight of steel turnings in the charge must be increased or diminished accordingly."

Process of Manufacture.

In practice the requisite amounts of the three ingredients of the charge are weighed out separately, the quartz and anthracite coal having previously been reduced to small fragments of a size varying roughly from that of a filbert to that of a walnut. After weighing, the different materials are thrown together into a heap on the floor of the furnace house where they are mixed as thoroughly as possible with a shovel. The resulting rough mixture is then thrown onto the top of the furnace a shovelful at a time, care being taken to heap it up around the vertical electrode or electrodes, as the case may be.

To receive the molten material when the furnace is tapped, a shallow bed of sand is prepared, either on the floor or, as was the case at one of the manufactories visited, in an iron box on wheels, which accordingly can be removed as soon as the tappings shall have to come to an end. Usually, however, immediately the flow of white-hot liquid has ceased, the surface of the resulting pool of molten alloy is skimmed to remove the layer of slag on the surface, a short, thick log of green wood fixed crosswise on the end of a long iron bar being employed for this purpose at the Keller-Leleux works.

As soon as the cake or slab of ferrosilicon has solidified, it is broken up with heavy iron hammers into comparatively small pieces, which in the case of the 50 per cent grade, at any rate, it has recently become the custom, at several of the works Dr. Copeman visited, to treat, while still hot, by immersing them in a bath of kerosene oil or melted crude paraffin.

This "pickling" treatment has been adopted on the assumption that by thus preventing contact with the air by means of a coating of oil or paraffin, it would prove possible to obviate the well-known tendency of certain samples of 50 per cent ferrosilicon to disintegrate spontaneously, and thus, incidentally, to prevent evolution of noxious gases, mainly phosphoretted and arseniuretted hydrogen, which under certain circumstances appear to be associated in specially large quantity with this particular grade of electrically produced ferrosilicon.

But as regards the prevention of the process of disintegration, the precise causation of which, by the way, is still to seek, the kerosene or paraffin bath treatment has not proved successful; while the fumes given off when ferrosilicon, which has been "coated" after this fashion, is subsequently heated, as appears to be considered before being utilized for its specific action on addition to a bath of molten steel or iron, are most objectionable, owing to the crude material usually employed. In addition, the heating of the alloy thus rendered necessary before use at ironworks must obviously promote in special degree the evolution of poisonous gases, and thus prove a special source of danger to workmen engaged in handling the material, and to whom this preliminary treating of the alloy is entrusted

In view, therefore, of the complete futility of this process of "pickling" for the intended purpose, coupled with the fact that it may actually involve, later on, an added source of danger to workers in the iron foundries, it is certainly desirable that the method should be abandoned.

Evolution of Gases from Ferrosilicons.

Concerning the evolution of obnoxious or dangerous gases from ferrosilicon under the influence of moist air, especially when accompanied by friction, Dr. H. Wilson Hake states in his report that the following gases have been alleged to be evolved: Phosphoretted hydrogen (PH_3), arseniuretted hydrogen (AsH_3), siliciuretted hydrogen (SiH_4), acetylene (C_2H_2), and hydrogen. In the numerous samples which he has examined, he has not found, however, any acetylene or siliciuretted hydrogen, and he does not believe they are evolved. All his evidence seems to show that the poisonous emanations evolved from ferrosilicon by the action of water consist mainly of phosphoretted hydrogen; sometimes alone, but for the most part accompanied by varying proportions of arseniuretted hydrogen.

The formation of these gases is due to the presence of small quantities of certain impurities in the coal, iron and quartz, used as starting materials; and in this respect the most important impurities are calcium phosphate and arsenic.

Calcium phosphate $Ca_3(PO_4)_2$ one of the impurities present in coal and in quartz, which in itself is a perfectly harmless salt, insoluble in water and widely diffused in nature, is responsible for the production of a dangerous compound by reduction in the electric furnace, in the presence of carbon, to calcium phosphide (Ca_3P_2).

This calcium phosphide remains in the ferrosilicon, and in contact with water or moist air is decomposed with evolution of phosphoretted hydrogen (PH_3), with an intensely poisonous character.

Arsenic again, an element closely allied with phosphorus in its properties, is another impurity liable to be present in various combinations in coal and in iron, and this element also finds its way into the ferrosilicon apparently as calcium arsenide. Calcium arsenide is also decomposed by water or moist air, evolving arseniuretted hydrogen (AsH_3), a gas scarcely, if at all, less poisonous than phosphoretted hydrogen.

Specific Gravity of Ferrosilicons.

The variations of hardness and of specific gravity of alloys containing different percentages of silicon are quite characteristic and may be used as a rough indication of the approximate composition.

The specific gravity decreases as the percentage of silicon increases, which obviously follows from the fact that the specific gravity of pure iron is 7.8 while that of pure silicon is 2.49.

Fig. 4 gives the results of Dr. Hake's determinations of the specific gravity of various samples of commercial ferrosilicon in comparison with the theoretical curve (the thick line in

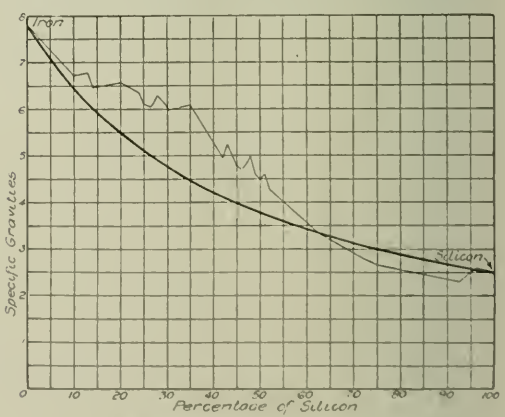

FIG. 4.—SPECIFIC GRAVITY OF FERROSILICON.

Fig. 4) representing the calculated specific gravities for all percentages on the assumption that mixtures of iron and silicon are formed without change of volume.

A comparison of the two curves demonstrates, what is indeed already well known, that such is not the case and the specific gravities are partly above and partly below the theoretical curve, showing that contraction of volume has occurred in the alloys formed up to 60 per cent silicon and expansion of volume from this to 96 per cent silicon, presumably owing to the presence of definite silicides of iron in the alloys.

Microstructure.

Mr. Samuel R. Bennett's report gives further confirmation of the general character of the specific gravity curve and also discusses the microstructure of ferrosilicons. Fig. 5 is Guertler and Tammann's diagram. Mr. Bennett gives some interesting microphotographs of various ferrosilicons and then sums up his conclusions as follows:

The various percentage grades of ferrosilicon are substantially binary alloys.

Two compounds, Fe_2Si and FeSi, exist; the former corresponding to 20 per cent Si, and the latter to 33.3 per cent Si, by weight. Microstructure also indicates the existence of two

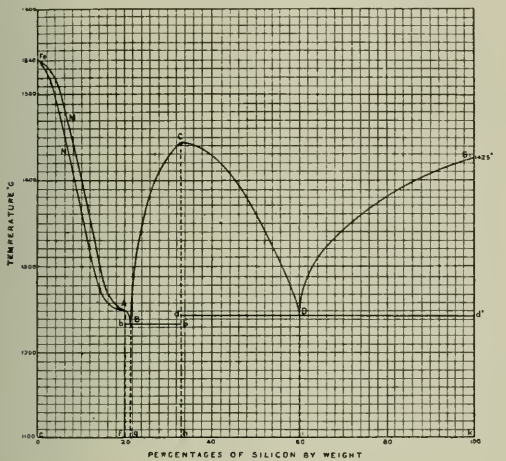

FIG. 5.—FERROSILICON DIAGRAM.

eutectics, one consisting of Fe Si and FeSi, corresponding to 21.6 per cent silicon approximately, and the other consisting of FeSi and Si at 60 per cent silicon.

Investigation of the specific volumes of various grades of alloys does not indicate the presence of other compounds.

Up to 20 per cent Si the alloys consist of solid solutions of Fe and Fe_2Si which are hard, firm masses giving off little or no gas. Alloys from 20 per cent Si to 21.6 per cent Si consist of primary crystals of Fe_2Si in ground of eutectic composed of Fe_2Si and FeSi; these alloys begin to get more brittle than the lower grades. From 21.6 per cent Si to 33.3 per cent Si the structure shows FeSi surrounded by eutectic Fe_2S and FeSi; from 33.3 per cent to 60 per cent Si there are crystals of FeSi in eutectic FeSi + Si; and above 60 per cent Si crystals of Si in field of eutectic FeSi and Si.

The amount of gases given off by different grades of ferrosilicon depends not only on the impurities present in the materials used in the electric furnaces, but also in the physical properties of the alloys, in consequence of which, in certain cases, access of moisture is afforded to a much larger extent of surface.

Hardness.

By the term "hardness" Dr. Hake implies the resistance offered to mechanical disintegration, or in other words, the varying difficulty experienced in breaking up and powdering the samples. To give two extreme instances, a sample with 26.5 per cent Si required a steel ore-crusher to break it up before it could be powdered, while a sample with 50 per cent Si could be crushed between the fingers.

Up to 30 per cent silicon content, the samples are more or less refractory without exception. There is an absence of any tendency on the part of these grades of ferrosilicon to disintegrate spontaneously.

Similarly, from 70 to 96 per cent where the silicon is in excess, although the samples are more or less brittle, they are not so easy to break up and to reduce to powder as those containing between 42 and 60 per cent silicon, and they also do not show a tendency to disintegrate spontaneously.

On the other hand, the samples containing from 42 to 60 per cent show a distinct tendency to spontaneous disintegration. They crumble on keeping, and some of them actually fall to powder after the lapse of a few weeks or months. This spontaneous disintegration is usually accompanied by a very noticeable evolution of evil-smelling and poisonous gases.

It has been alleged that the same phenomenon is apt to occur with 33 to 35 per cent grades, but Dr. Hake has no personal experience of the fact.

Transport and Storage of Ferrosilicon.

In view of the accidents which had happened, four of the large ferro-alloy manufacturers of France (Giffre, Girod, Keller-Leleux, La Volta) formed a special committee which came to the conclusion to propose "to give up making dangerous grades completely, which now are known to be those ranging from 30 to 40 per cent, and from 47 to 65 per cent."

"By discarding these specially dangerous grades and ceasing the manufacture of 30 to 40 per cent and 47 to 65 per cent ferrosilicon, there would remain nothing but perfectly compact alloys as free from danger to transport and to warehouse as ordinary pieces of cast iron."

These recommendations have been accepted by eight other French manufacturers, so that in all 12 French firms have agreed upon the above recommendations.

Dr. Copeman for the British Government Board goes even further in his recommendations. He is of the opinion that "the conclusion is justified that the manufacture of ferrosilicon should, at present, be restricted to the production of percentage grades of 70 per cent and upward at one end of the scale; and, at the opposite extremity, up to and including 30 per cent, on the supposition that under certain circumstances the employment of a comparatively low grade may be desirable or necessary. . . .

"But as, pending international agreement on the question, intermediate percentages of ferrosilicon will doubtless continue to be manufactured and sold, the issue, by the Board of Trade, of special regulations will be necessary in order to obviate, so far as may be possible, chance of further accidents during the transport of this substance."

The following regulations are suggested by Dr. Copeman:

"1. Ferrosilicon should not be sent out from the works immediately after manufacture, but, after being broken up into pieces of the size in which it is usually sold, should be stored under cover, but exposed to the air as completely as possible for at least a month before being dispatched from the works.

"2. Manufacturers should be required to mark in bold letters each barrel or other parcel of ferrosilicon with the name and percentage grade (certified by chemical analysis) of the material; the name of the works where it is produced; the date of manufacture, and date of despatch.

"3. The carriage of ferrosilicon on vessels carrying passengers should be prohibited. When carried on cargo boats, it should, if circumstances permit, be stored on deck. If it be considered necessary to store it elsewhere, the place of storage should be capable of being adequately ventilated, and such place of storage should be cut off by airtight bulkheads from the quarters occupied by the crew of the vessel.

"4. This regulation should apply to the transport of ferrosilicon on river or canal barges as well as on sea-going vessels.

"5. Storage places at docks or at works where ferrosilicon is used should have provision for free access of air, and should be situated at a distance from workrooms, messrooms, offices, etc.

Elsewhere in his report, Dr. Copeman makes the following remarks, which may be mentioned in this connection: "So far

as I am aware ferrosilicon is no longer packed in closed iron drums, so that, to this extent, likelihood of explosion is avoided, but as in transport, even when packed in wooden barrels, a considerable amount of friction must inevitably occur between the rough lumps, in which form the ferrosilicon is ordinarily sent out from the works, I would offer the suggestion that, in the course of packing the alloy into barrels, all interstices might usefully be filled in with shavings, wisps of hay, or other similarly cheap material."

A brief comment on the situation of the ferrosilicon industry in this country will be found on our editorial pages.

On the Preponderance of Nullovalent Matter.

By Dr. Gustavus Hinrichs.

For more than a thousand years chemists of all schools and creeds have experimented on all sorts of ponderable matter under all conditions conceivable, without ever meeting any form of matter which resisted all means of producing chemical changes.

Chemists have, therefore, concluded that all ponderable matter is chemically active, and can, with greater or less readiness, be subjected to entire cycles of chemical transformations, producing more and more complex substances in ascending cycles and obtaining finally, by descending cycles, ponderable matter in the simplest form known, namely, the chemical elements.

Hence chemists have, during the last two centuries at least, held that all ponderable matter is chemically active, and that the chemical elements are simple and irreducible substances.

Two New Fundamental Conclusions.—For more than half a century I have recognized the latter conclusion to be erroneous and for more than a third of a century I have found that the first conclusion cannot be true, and that on the contrary we shall have to admit:

I. Ponderable matter is not chemically active except under very special forms, affecting at most a hundredth of all matter.

II. Matter is one; hence the chemical elements are not simple substances, but combinations of several degrees of one single substance, the Pantogen.

This latter conclusion I have tried to demonstrate in my publications for now more than half a century.

As to the first conclusion, it is known since 1894 that there exist small amounts of a few nullovalent chemical elements. This is the argon group, or argonoids, comprising: Helium, neon, argon, krypton and xenon. The so-called emanation of radium is also nullovalent; but is of an entirely different order, as we expect to show shortly.

Still it remains generally understood that these nullovalent elements are exceedingly rare, though they seem to be widely diffused.

Accordingly, the exception from the old rule, that all ponderable matter is chemically active, appears to be quantitatively of little importance, though sufficient to prove that the old conclusion is not absolutely correct.

So far as we ourselves are concerned, the discovery of nullovalent elements had been expected for more than twenty years; for we have published it implicitly in our Molecular Mechanics, Davenport and New York, 1874; see section XVIII: The Element Atom an Atom Crystal, pp. 178-182.

The Nullovalent Elements in 1874.—In the work of 1874 specified, the four elements Fl, O, N, C are (p. 180-181) compared with the simple organic radicals, CH_3, CH_2, CH, and the tetravalent C, as derived from the saturated (nullovalent) methane CH_4, according to their atomic weight a and their valence n

"If we generalize this, we can express the atomic weight a of these elements by the formula

$$a = 2(10-n) = 20-2n$$

Valence	$n =$	1	2	3	4
Calc. at weight	a	18	16	14	12
Obs. at weight		Fl—1	O	N	C"

"502.—Now, this corresponds exactly to the organic radicals—namely, if we start from the saturated methane, $CH_4 = 16$, we have $a = 16 - n$, namely,

Atomicity	$n =$	1	2	3	4
Atomic weight	$a =$	15	14	13	12
Radicals		CH_3	CH_2	CH	C

"It is evident that the graphical symbols (Fig. 1, line F, Plate I) might completely represent the above elements, if the *dot* stands for two—i. e., four pantogen atoms * * * while the *cross* stands for twelve, some aggregation of pantogen atoms in the shape of a square prism for one end of which one of the four corners has been removed. It will be seen that this not only accounts for the atomic weight, but also for the atomicity of these most important elements."

In paragraph 503 of the same work, the probable structure of the sulphoids (O, S, Se, Te) is given; in 506 that of the Kaloids (Li, Na, Ka, Rb, Cs), while in 504 the increase 16 is defined, and 505 gives the general law of the addition by 3 times, 3 times, 2 times, 3 times, in the three highest members of each genus of elements and the explanation of the fact exactly as we have given it in our latest publication on this subject: The Proximate Constituents of the Chemical Elements, 1904. These references will be sufficient at this time and in this brief note.

The parallel between the elements and the organic radicals being complete, it is implied that a nullovalent element must correspond to the saturated CH_4, especially as the formula includes the elements of opposite (negative) valence, namely:

Valence	$n =$	—1	—2	—3	—4
Calc. atomic weight	$a =$	22	24	26	28
Observed		Na—1	Mg	Al—1	Si

These two groups of four each of chemical elements must therefore be connected by a nullovalent element of the atomic weight of 20. This element is known as Neon.

The case is much stronger still. For if we subtract from the constant 20 the common rise of 16 in the atomic weight of the consecutive groups, we obtain the corresponding formula

$$a = 4 - 2n$$

giving the values,

Valence	$n =$	—1	—2	—3	—4
At. wght. calc.	$a =$	6	8	10	12
At. wgt. observed		Li—1	Be—1	Bo—1	C

and requiring a nullovalent element for $n = 0$ of the atomic weight 4. This evidently is our helium.

These relations contained in my formulæ and figures printed in the work of 1874, as quoted, were quite familiar to me and their bearing was well understood; but it was absolutely impossible, at that time, to state my conclusion. In fact, I shall mention, my experience in 1908 proved that I was too hasty even then, when I was ready to furnish positive proof, as we shall see soon.

What I dared to proclaim in 1874 was more than the chemical public could take; only Berthelot requested me to furnish him certain specified portions of that work for publication in the *Annales de Chimie et Physique*. This was not done, because my time was in 1875 so fully taken up by the collection and study of the Amana Meteorites.

I will mention just one striking experience, which made me hesitate to give further early details of my investigations. My Atommechanik of 1867 was denounced in the *English Weekly Chemical Journal* by the editor, who had never seen the work. It is evident from his statements, he had only the English Resumé, and devoted most of his attention to the historic introduction which is no part of the work itself. Some critics are in every way more free to move the less they are loaded with knowledge of their own and the less they have seen of the work they want to condemn.

It is precisely this condition of things that has now come home to their readers and subscribers, who have been kept in the dark about what has been done, greatly to their disadvantage, even in their own investigations.

Upon the publication of the discovery of Argon in 1894, I

exposed the above relations in a special public lecture, and predicted that it would be but the first of that entire group of nullovalent chemical elements implicitly contained in my Molecular Mechanics of 1874.

The first time I explicitly mentioned my principle of the high preponderance of nullovalent matter over chemically active matter in Nature was in a letter of April 15, 1908, to a prominent chemist of Paris. That chemist never inquired further about it.

The Nullovalent Matter of the Chemically Active Elements.—The formula and figures published by me during the past half century show plainly that the element atoms of a group or Genus have a common active head, and differ only in the growth attained in their bodies, which growth goes by regular additions of very nearly $a:3a:3a:6a$, if the element belongs to what I term heavy or common elements. In the lighter elements, the additions are $a:a:3a:3a:6a$. In all cases, a is nearly 16.

These statements may be verified by an examination of my Principles of Chemistry and Molecular Mechanics of 1874; the Pli-Cacheté of 1891 (published, 1907); True Atomic Weights of 1894, and The Proximate Constituents of the Chemical Elements, of 1904. All my deductions of the physical, chemical and crystallographical properties of the elements are based upon this general structure. We can not go into further details here.

Since the chemical character of an element depends on the head only, all these additions are chemically inert or nullovalent. That is: in the Kaloids, the chemically active matter can not be more than what there is of it in an atom of Lithium. But by no means is all the weight of a lithium atom chemically active.

By my recent researches I have been able to prove that, in a hydrogen atom, the chemically active part is less than 1 per cent (*Comptes Rendus*, T. 147, pp. 797-800, 1908).

This percentage is not likely to be greater in an atom of lithium (as a matter of fact, it is demonstrated now to be much less than 1 per cent). Since the chemically active part in all kaloid atoms is the same, it cannot be more than 7/23, say 1/3 per cent in Na; 7/39 or 1/6 per cent in Ka; and not more than 1/20 per cent or half a pro mille in Cesium.

In other words: the total amount of chemically active matter is much less than 1 per cent of the total ponderable matter in existence. That is: chemically nullovalent matter is not an insignificant small fraction of the ponderable matter of the universe, but constitutes more than 99 per cent of all matter.

After waiting more than thirty years before speaking of this decidedly strange result, I found that I had been altogether too hasty. The details of this, my experience, are quite interesting to me and are likely to be so to others in a near future; but we have no place for them here and now.

Right here and just now the reader will possibly say that I have not proved my statements about the great predominance of chemically inert matter over the chemically active ponderable matter. I fully sympathize with the reader; for I know exactly what is the difficulty in his way, and will do all I can to clear the road.

First, the reader is in the position of a student listening to a demonstration of a geometrical proposition while not familiar with geometry; he cannot see the force of the demonstration.

Now, in that sort of a case, I have found it quite useful to show by some simple measurements or weighings, on models, that the proposition holds good in such special cases.

I shall do that very thing in a concluding article next month, in which I shall determine the weight of the amount of active matter in the atom of silver and of other chemical elements, which alone is characteristic of its chemical activity.

In the meantime I would respectfully request the reader of the present note to lay this paper aside, and to read it very carefully once every week till the next issue comes to hand; I dare say that the reader will gradually feel at least some of the force of the reasoning here employed.

By this process the reader will also have prepared himself for the more ready understanding of the mode of calculation that will be used in the closing paper.

Just think for a moment on the difficulties in the way of understanding the form of the earth and the position of the antipodes—a thousand years ago. In science we have to wrestle with such apparent difficulties at every big step we take forward into greater light.

St. Louis, Mo.

Pulp Classification and Tube Mill Efficiency.

In an interesting paper presented to the Mexican Institute of Mining and Metallurgy (Informes y Memorias del Instituto Mexicano de Minas y Metalurgia, Vol. 1, No. 3, December, 1909), Mr. V. B. Sherrod reports on some features of the extended research work which has been done at the Guerrero Mill, Pachuca, Mexico, particularly in the direction of pulp classification and in ascertaining the efficiency of tube-mill work under varying conditions.

The flow-sheet on page 140 illustrates clearly the sequence of the various operations and is self-explanatory.

Table I, "Screen Analysis of Samples," shows the average screen, or grading analyses of several sets of samples taken during the month of July, 1909, at the Guerrero Mill, the various products at each step being carefully sampled. A study of the figures will show some very interesting features.

Special attention is called by Mr. Sherrod to the work of the Callow screens, which at 100 ft. belt travel per minute (a very high speed) when equipped with 30-mesh, No. 33 steel wire (the purpose being to separate as undersize all material that can be made to pass a 40-mesh laboratory screen) gives an oversize 92 per cent of which remains on a 40-mesh screen and 96.5 per cent remains on 60-mesh screen. At the same time an undersize is sent to the hydraulic cones, 9½ per cent of which passes a 40-mesh, said product containing practically all of the liberated mineral. The effect of this system is seen in the enormously wide streak of mineral on the first three Wilfley tables, which really receive as feed a product that has once been concentrated by the Callow screens and once by the hydraulic cones following these.

Another feature of interest to concentrator men is the analysis of the product of the Chilean mills, 4 per cent of which remains on a 40-mesh screen and 32.4 per cent of which passes a 200-mesh screen notwithstanding that a 30-mesh "ton-cap" screen is used in the mills. The discharge through these screens is kept up to the maximum, a heavy splash being used, but all material coarser than 60-mesh is, so far as possible, cut out in the first hydraulic classifiers following these mills and sent back to the Wilfley tables, where it joins the oversize from the Callow screens and returns again to the Chilean mills.

Another feature of the grinding at Guerrero Mill is the fineness of the tube-mill feed, only 7 per cent of which remains on a 60 screen. This is, of course, absolutely against high tube-mill tonnage, but is justified by the necessity for the most careful possible concentration, which means on these ores pretty fine grinding (in stages) and careful elimination after each step and before the tube mills get a chance to slime the mineral. The apparently low efficiency of the tube mills receiving such feed (in comparison with, for instance, the Loreto Mill of the same company, in which a much simpler flow-sheet is in use) is principally due to the fact that all of the easily slimed portion of the ore has been made to pass a 200-mesh screen during its repeated passage through the Waddell mills, leaving for the tube mills nothing but the most refractory portion to grind.

Tube Mill Operations, Screen Analysis of Feed and Discharge.

The Table II is made up from sampling done at Loreto Mill on various dates, and does not furnish absolute comparison with the performance of the Waddell mills above mentioned, on account of the difference in grinding systems employed and also

because the ores fed to these mills are much more friable than those ground in the Guerrero mill. The object of the test was to determine the most efficient feed for the tube mills and to furnish comparison between the tube mills differing from each other in make and leading dimensions, especially diameter.

The samples from which the analyses were obtained were taken in sets, and for obvious reasons, such as daily variations in the character of the ore, etc., too close comparisons should not be made between analyses of samples of different sets. Some sets of samples must also be eliminated from any comparisons whatever, because conditions changed so frequently during the two or three hours consumed by the tests that determination of kilos per minute of solids fed to mill, percentage of solids, etc., are not accurate. Such tests are indi-

a This mill was equipped with wornout rings from other mills.

cated by marginal notes. Despite these disabilities, however, it was possible to collect much valuable data.

The determination of the most favorable feed for horse-power efficiency was naturally the first consideration, with special reference to the percentage of solids in the feed and the kilos of dry feed per minute for each different mill. A little study of the table leaves no doubt as to these points, except in the case of No. 4 mill (D. E. W. Company, 5 ft. x 20 ft.) wherein the value of these tests was practically destroyed by the variations of feed above referred to. Therefore, the tests on this mill are given for what they are worth, demonstrating as they do the horse-power efficiency of the mill does not increase with the quantity of dry feed up to an undetermined point.

Briefly, the conclusions which may be safely drawn from the series of tests are as follows:

1. That the grinding efficiency increases with the percentage of solids in the feed up to approximately 55 or 60 per cent.

2. That the grinding efficiency increases with the quantity of ore fed per minute to a point which varies with the dimensions of the mill, and that beyond this point capacity is not gained, and within reasonable limits there is no loss except that due to the return to the mill of an excess of oversize.

The limit of profitable feed varies with the character of the pulp, and it is only possible to determine this limit for any mill by special experiment with the ores for which the mill is intended.

At the Loreto mill the profitable feed for the 4-ft. x 18-ft. mill was apparently 80 kilos of solids per minute, or at the rate of 115 metrical tons per 24 hours, although heavier feed did not reduce the efficiency of the mill. The limit for the two 4-ft. 6-in. x 15-ft. mills was not proved, but is apparently somewhat lower than the correct feed for No. 1 and is probably due to the

a Fed at less than capacity to determine the efficiency of mill. *b* Same as *a*. *c* Same as *a*. *d* Fed at less than capacity to determine effect of per cent. of solids in feed. *e* Fed at less than capacity to determine effect of various feeds. *f* Same as *e*. *g* Fed at less than capacity for same purpose as *e*. *h* Determinations of feed per minute vitiated by power troubles during test. *i* Power troubles during test. *j* Determination of feed not correct, power troubles

fact that they are 3 ft. shorter, which reduces the capacity somewhat, and they have a greater diameter, which tends toward a reduction of their horse-power efficiency.

This statement as to horse-power efficiency is not absolutely proven by the above tests, but in every case the efficiency has been lower in mills of greater diameter, except one in which the small mill did not have more than about 60 per cent of its most economical feed.

The 5-ft. x 20-ft. mill (which is mechanically the best built one) has shown in every comparative test a lower grinding efficiency than the smaller mills, but it would not be fair to look upon this deduction as final, owing to reasonable doubt as to the accuracy of determination of quantities.

Screen Tests on Waddell Chilean Mills.

These tests, shown in Table III, were made to determine the best feed for these mills, and it requires but a superficial examination to decide that the heaviest feed which can be taken care of by the discharge screen in use is the most economical one. In fact, based on the results of these tests, the entire launder system for distributing the feed for these mills is being replaced by a "distributing tub" system designed to do away with the inequalities of the launder system and to permit every mill to receive at all times as near as possible its maximum feed.

The mill efficiency in the above tests was computed in kilos per minute, ground to pass a 200-mesh wire screen, not as a definite standard, but as a convenient means of comparison for the different mills.

A Reichsgericht Decision on the Scope of the Patent Treaty Between the United States and Germany.

In our correspondence columns in this issue "Manufacturer" refers to a recent Reichsgericht decision of considerable importance with respect to the patent treaty between this country and Germany. The Reichsgericht is the German Supreme Court, and the decision in question was rendered in the patent litigation of the National Cash Register Company, of Berlin, defendants, now the National Cash Register Company, of Dayton, Ohio, appellants, against Schubert and Salzer, complainants and appellees, regarding withdrawing the German patents 119,260, and 119,155.

These patents, which refer to improvements in cash registers, were taken out in the name of the National Cash Register Company, a limited company, the place of business of which was Berlin.

On July 16, 1907, the complainant (Schubert and Salzer) moved that the patents should be withdrawn according to § 11, No. 1, of the German patent law, because at that time (more than three years after the publication of the granting of the patents) the inventions were not worked in Germany to a sufficient extent. All the essential parts of the cash registers protected by the patents were manufactured by the American parent company, the National Cash Register Company, of Dayton, Ohio, and were imported to Germany from this country.

The German Patent Office, in a decision of May 11, 1908, ordered the withdrawal of the patents according to the motion of the complainants, Schubert and Salzer.

Against this decision of the German Patent Office the National Cash Register Company, of Berlin, appealed. After the papers had been submitted to the Reichsgericht and after a date for the oral hearing had been arranged, the name of the firm owning the patents underwent a change. The firm name is now the National Cash Register Company, Ltd. This change was registered in the Patent Office and in the papers in this suit. Further, all four patents were assigned on May 25, 1909, by the National Cash Register Company, Ltd., in Berlin, to the National Cash Register Company, of Dayton, Ohio, which is the American parent company of the Berlin firm. Accordingly the ownership of the patents was also changed in the registers of the Patent Office to this American firm, and the assignment of these patents was published in the *German Imperial Gazette* of July 29, 1909.

Further, on Aug. 1, 1909, in No. 47 of the *Imperial Gazette*, the patent treaty between the German Empire and the United States concerning mutual industrial protection, which took effect on Feb. 23, 1909, was published.

The oral arguments of the attorneys, in accordance with the direction of the Reichsgericht, were restricted to the question whether this patent treaty should influence the decision in the suit concerning these two patents, and, if so, what kind of an influence the patent treaty should exercise.

The German Reichsgericht, in its decision rendered on Nov. 21, 1909, reversed the decision of the German Patent Office and denied the motion to withdraw patents 119,155 and 119,260.

In the decision of the Reichsgericht the question is first discussed whether the American firm should be admitted as the principal party in this suit for the reason that the American firm is now registered as owners of the patents in the Patent Office; or whether, in view of the opposition of the complainant, this should not be done. The Reichsgericht decided on the basis of a lengthy argument on the applicability of certain paragraphs in the German patent law and the German civil law that "the opposition of the complainant against the admission of the American company as defendant in this suit is to be disregarded, and it is decided that this latter firm is the main party entitled to defend the patents."

"As far as the subject-matter itself is concerned, the withdrawal of the patents, even after it had been justly decided by the Patent Office, based on § 11 of the patent law, cannot be affirmed by the court, after the treaty between the German Empire and the United States of America referring to the mutual industrial protection, dated Feb. 23, 1909, has taken effect on Aug. 1, 1909, and after the patents have been assigned to the present owner.

"The treaty which has been passed by the Federal Council and by the Diet, and which has been published in the *Imperial Gazette*, is legally binding. It is provided in article 1, sentence 1, that those laws of the one country of the high contracting parties which decree the withdrawal or other restrictions in case of non-working of a patent or other protective rights, should apply to patents belong to citizens of the other high contracting party, only as far as patents belonging to citizens of this country are affected by their own laws. The effect of this provision for the patents which are here under discussion becomes evident from the circumstance that according to § 11 of the German patent law the owner of the patent is obliged to work his invention to an adequate extent, if he does not want to lose his patent rights, but that, on the other hand, there is no working clause in the United States. As appears also from the memorandum with which the Imperial Chancellor submitted the treaty to the Diet, this treaty sets forth that American citizens are freed from the provisions of the German law regarding the working clause. As it is there further stated, 'they are hereby placed on an equality with the German citizens who obtain patent protection in the United States without any obligation to work their patents,' therefore the treaty provides that the working clause which is decreed by the German law does not apply to patents belonging to a citizen of the United States. Because in his home country the working clause does not exist, he is not subjected to the German provisions for a working clause on account of his nationality.

"The question whether the provisions of this treaty should affect this suit which has been started before the ratification of the treaty will be discussed later on. If we at present disregard this point, it would follow that for the reason that the patents in question now belong to the American firm, the motion for the withdrawal of the patents would not succeed. The complainant opposes this and asks for a different interpretation of the treaty from two points of view.

"First, the complainant contends that the treaty only speaks of patents which have been 'granted' to citizens of the other country. This means to the applicant for the patent or to that person to whom the patent has originally been granted, but it seems to exclude later assignees, such as the present complainant. This point is not well taken. It is contradicted by the English text, which is also published in the *Imperial Gazette*. This reads: 'Patents enjoyed by the citizens of the other contracting party.' That means patents the ownership of which is enjoyed by the citizens who possess them. * * *

"The complainant has further argued that in the treaty the expression 'citizens' has been used and that citizenship is a quality which is inherent only to physical individuals and since the present defendant is a corporation doing business in the State of Ohio under the American law, it cannot be a 'citizen.' But this argument must also necessarily fail. The point whether the terms 'citizens,' 'subjects,' used in treaties apply to physical persons only has been already adjudicated and denied by the Imperial Court. * * * It must be decided that any corporation or company doing business within the territory of any two countries and incorporated under the laws of the country must be considered 'citizens' within the meaning of the treaty.

"A third restriction of the treaty, which, however, has not been argued by the complainant, has been mentioned in a publication of the *Zeitschrift für Industrierecht* (1909, page 229). It is there contended that an American is only freed from the working of his German patent if he owns at the same time a corresponding home patent. The testimony in this suit differs as to the question whether such is the case with the patents in litigation, so that further testimony would have to be taken if this point were argued. But the point is not well taken. * * *

"Finally, the question must be considered whether the provisions of the treaty should apply in a suit which has been brought before the treaty took effect, and in which suit the courts of the first instance has already rendered an unfavorable decision. In this respect it must at once be denied that new laws enacted in favor of the citizens of the United States are only effective for patents which are applied for or granted after the treaty took effect. Neither the context nor the purpose of the treaty allows such a restricting interpretation. Evidently the purpose of the treaty was to make the freedom from the working clause unrestricted, at least from now on, and to enforce this freedom also in case of older protective rights. It is only debatable how the treaty affects patents which have existed beyond the limit defined in § 11 of the patent law and which, within these limits, have not been worked, so that according to the present law a motion for their withdrawal would be allowed, as has been the case with the patents here in suit.

"In answering this question, the general principle must be considered that new laws must not affect well-acquired private rights. This would apply, if complainant after the lapse of three years, during which the patent had not been worked, would have acquired a private right regarding the withdrawal of the patent. But this is not so. A private right for the withdrawal of a patent does not exist. The withdrawal possesses the nature of a popular complaint which the individual only exercises for the benefit of the general and public interest. A patent 'may' in case of certain legal presumptions be withdrawn, but it must not be done necessarily. The court possessing jurisdiction may not insist on withdrawing, if considering the individual case it concludes that the public interest of the home country is not injured or if it decides that the owner of the patent alleges good reasons for non-working. A decision lies within the free judicial discretion and it must be rendered strictly in accordance with the facts prevailing at the time of rendering the decision. Especially for the higher instances of the court, the circumstances prevailing at the time when the decision is rendered, are binding.

"The question what is to be considered as public interest might be differently answered. It may be held of primary importance that the patent law should serve the national industry and that it must help to increase domestic welfare by increased opportunity for labor; or it may be held that the free international exchange of all technical progress and the new products which are obtained in this way may be the first consideration. In this regard the courts must judge in accordance with the existing laws. The patent law in § 11 sanctions the protection of the national industry. Nobody must be permitted to utilize a patent to the exclusion of others. The inventor must within a certain time work the invention at home. The Paris International Convention for the Protection of Industrial Property and the Brussels additional treaty confirmed this principle. The treaty with the United States, however, supports the second point of view. By granting to the American industry which by their domestic laws is freed from the working clause certain privileges in Germany which the national industry does not enjoy and permitting the American to utilize his German patents to the exclusion of the German industry, the treaty brings out other and new viewpoints for the definition of the public interest in relation to the industry of this country. After the treaty came ino force and during its duration, the German courts cannot enforce any more upon a citizen of the United States the protection of the German national industry as a public interest.

"For these reasons the motion to withdraw the two patents in suit must be denied."

This decision of the German Reichsgericht is a model of impartiality. The definition of the scope of "public interest" in the concluding part of the decision shows a spirit of enlightened self-interest and broad-mindedness which is admirable.

Notes on Chemistry and Metallurgy in Great Britain.

(*From our Special Correspondent.*)

The Institute of Metals.

The annual general meeting was held on Jan. 18 and 19, at the Institution of Mechanical Engineers, when the new president, Sir Gerard Muntz, delivered his inaugural address, in the course of which he said that the absence of a general knowledge of the non-ferrous metals was simply appalling; and a large field existed for young metallurgists in such metals. There was probably a larger extent of investigation before the Institute than was open to any kindred association.

In opening the discussion on the paper on "The Properties and Constitution of the Copper-Arsenic Alloys," by Mr J. D. Bengough and Mr. B. P. Hill (abstracted on page 95 of our February issue), Professor Huntington said he had a notion he had done some work on the subject some years ago. The first point attracting his attention was the statement that arsenic gave copper good working properties at high temperatures. His experience was that arsenic had a very bad effect on copper at high temperatures.

Mr. W. Rosenhain, with reference to the formation of cracks, said Professor Huntington's theory appealed to him rather than the authors' deduction. Raising the specified limit of arsenic could not be recommended without further research; and it would be essential to learn something more about fatigue and resistance to shock.

Mr. Rhead said that two or three years ago he was working on alloys of electro-copper containing from 0.5 to 1.5 per cent of arsenic. With 0.5 per cent distinct separation of arsenic compounds, on the borders of the crystals, took place. A similar segregation occurred when antimony was used. On two occasions he had had evidence of serious pollution of arsenic alloys by gases containing chlorine. At their first Birmingham meeting he had pointed out the serious effects produced by heating copper for long periods in reducing gases. The production of oxide accounted for the cracked appearances.

Mr. Bengough replied, as to the reaction between the oxide

and reducing gases, that there was a critical temperature at which the reaction took place. It did not occur below 600° C. He proposed to make his general reply in a written communication.

Mr. Ernest A. Smith's paper on **"The Assay of Industrial Gold Alloys"** followed. It was abstracted on page 92 of our last issue.

Professor Gowland attached a high value to this paper by reason of its containing much original matter hitherto unpublished. Mr. Smith was especially fitted for writing such a paper. The old Japanese 9-carat alloy contained gold and silver only, and the silver could be removed from the surface by pickling. The Japanese alloy now contains silver and copper. There was difficulty in taking a fair sample from a gold-silver-copper alloy; in fact, a dip sample was necessary. When silver only was alloyed with the gold the old touchstone test gave reliable indications for the assay.

Professor Turner concurred as to the great value of the paper, but regretted that any reference to cadmium in the alloys had been omitted.

The next paper read was by Dr. R. Seligman and Mr. F. J. Willott on **"The Analysis of Aluminium and its Alloys,"** in which the authors strongly urged the desirability of standardization of methods, and fully described the procedure they had found consistently reliable. (An abstract of the paper appeared on page 94 of our last issue.) The discussion was adjourned.

On the second day, Jan. 19, the first paper taken was on **"A Contribution to the Study of Phosphor Bronze,"** by Mr. O. F. Hudson and Mr. E. F. Law, who said that the object of their research was to investigate the relation between the constitution of the phosphor-bronze alloys and their mechanical properties. (See the abstract on page 95 of our last issue.)

Mr. A. Philip fully recognized the great value of the work carried out by the authors, but thought that the evidence they had produced of the existence of a triple alloy of copper, phosphorus, and tin, was not quite conclusive.

Dr. Rosenhain was also of opinion that the evidence adduced by the authors did not adequately support their conclusions. When the additional facts embodied in the full details of their work were placed before the Institute the authors would have made a most valuable contribution to the subject which would be of permanent interest.

Mr. Spence Thomas regarded the matter from the point of view of a user of phosphor-bronze. In his experience the life of bearings in hot mills, under exactly similar conditions, varied from 1 month to 15 months. He urged co-operation between producers and users in the hope of securing greater durability.

Professor Turner remarked that the differences in mechanical properties between the various grades of phosphor-bronze were as great as those between cast iron, wrought iron and steel. Whatever opinions might be entertained as to the existence of the triple alloy described in the paper, the fact remained that there was some constituent of phosphor bronze which disappeared and reappeared under varying conditions of heat treatment, and this fact was most important in connection with the subject.

Mr. Law replied that the matters referred to by Mr. Spence Thomas might be explained by the low melting point of the triple eutectic, viz., 620° C., the consequence being that bearings in which it occurred were not able to withstand the high temperature encountered in hot mills.

Mr. Spence Thomas said that when such bearings were used in cold mills their life also varied, and had been found both longer and shorter than in hot mills.

Mr. Gaywood attributed the trouble with the bearings to an excess of lead in the phosphor-bronze.

Mr. Law had arranged to illustrate the paper by lantern projections from colored photomicrographs on Lumière plates; but, unfortunately, the impracticability of securing sufficient exclusion of daylight, or a suitable disposition of the apparatus, did not permit of the desired degree of distinctness being attained.

Mr. T. Vaughan Hughes read a paper on **"Failure in Practice of Non-ferrous Metals and Alloys,** with Particular Reference to Brass Loco-Tubes." (Abstracted on page 94 of our last issue.)

Dr. Rosenhain, in the discussion, said he found difficulty in acquiescing in the view that a film of non-conducting substance one-tenth of a millimeter in thickness could so prevent the transmission of heat as to raise the temperature to 800° C. Had the author further examined the tubes from which the deposit had been scraped? If the theory were true, the effect of over-heating would be found at the firebox ends of nearly all the tubes, and such evidence, if forthcoming, would be almost conclusive. He did not concede that there was justification for assuming that overheating occurred only after the tubes came from the makers.

Professor Turner said the thinning of the tubes might be attributed to various causes. Abrasion by particles of clinker was one; and for another there might be chlorine in the gases. Examination of the films on the surfaces of tubes undergoing corrosion would show the presence of a considerable quantity of chlorine. If lead were present it certainly caused failure; but corrosion was known to occur in tubes which were commercially pure. Tubes were cold-drawn, the ends were expanded afterwards, and the damage was often caused by the final annealing.

Professor Huntington agreed that the annealing was probably responsible for troubles. The usual difficulty was in getting a continuous history of the material from its manufacture to its use.

Mr. Heathcote remarked that, from a paper recently read before the Society of Chemical Industry, it appeared that oil in the feed-water had caused the tubes to attain a temperature so high that globules of molten copper were found on their fire-sides. This represented 1000° C.

Mr. Bengough said that overheating, doubtless, occurred during the expanding. The strength of the material was not very much affected at ordinary temperatures; but under stress at high temperatures it was seriously deteriorated. He considered that prolonged heating at a moderate temperature would produce the same structure as heating for a short period at 800° C.

The president observed that he had experienced corrosion from the outside of the tubes; he had known tubes to have been corroded quite through where alkaline water was used. The Midland Railway had had much difficulty in that respect. As to the effect of chlorine, the old tubes returned had chlorides as well as sulphides in the tube.

Mr. Vaughan Hughes explained that the fuel used was coke. No chlorides of copper or zinc were found, but sulphate and chloride of calcium.

Institution of Mechanical Engineers.

Alloys Research Committee.

Mr. E. B. Ellington presided at a meeting of this Institution on Jan. 21, when the ninth report of the Alloys Research Committee was presented. It deals with the properties of various alloys of copper, aluminium and manganese, and corrosion of copper-aluminium alloys by sea-water.

Sir W. H. White, chairman of the committee, said the work of that committee was to so conduct the research that the chief results would be of practical utility to mechanical engineers. Some of the earlier reports had, he thought, been unjustly criticized in that respect. The results of the work done were so stated as to be capable of being applied commercially in the manufacture of non-ferrous metals.

Sir Gerard Muntz stated that his practical experience enabled him to confirm some of the results arrived at in the report. His firm was making aluminium castings for motor cars, and

great difficulty had been encountered in the heat treatment. The cutting qualities of some of the alloys had considerable interest for him; and that was a point which, among others, he should try to follow up as a manufacturer.

Prof. J. O. Arnold remarked that the work which had been done was in a direction new to engineers.

It appeared that from a mechanical point of view they must not expect too much from micrographical analysis. Molecular changes, both in ferrous and non-ferrous metals, demanded investigation in the interests of public safety. Such changes were often not detected by the usual tests, but had a serious effect on the properties of metals.

The discussion stands adjourned to Feb. 18.

Market Prices.

Copper.—Starting at close on £62 per ton, the price of standard fluctuated frequently, though not to great extent, up to Jan. 12, it then commenced to fall, but picking up slightly on the 18th, recovered ultimately to £60 17 6.

Tin.—Dropped smartly from the opening price of £153 to £148 10 0 during the first three days; then recovered to £151 7 0, after which fairly steady fall to £147 10 0.

English Lead.—Flat throughout the month at £14 to £14 3 0, closing £13 7 6.

Iron, Cleveland Warrants.—Rose fairly steadily from 51/- to 52/3.

Scotch Pig.—Followed much the same course as Cleveland, i.e., during the month (6th to 13th and 20th) carrying the price from 62 6 to 65/-; closing at 67/-, but little doing at this price.

Aluminium ingots, in ton weights	£75	0	0
Antimony, black sulphide powder, per ton	20	0	0
Sulphate of ammonia, f.o.b. Liverpool, per ton	11	12	6
Copper sulphate, per ton	19	15	0
Caustic soda, white, 77 per cent, per ton	11	2	6
Bleaching powder, 35 per cent, per ton	4	5	0
Shellac, standard T. N., orange spots, cwt	3	8	6
Carbolic acid, liquid, 97 to 99 per cent, gal			11
Creosote, ordinary good liquid, gal			2⅜
Naphtha solvent 90 per cent at 160° C., gal		1	3½
Rubber, Para, fine, lb		7	8
Platinum, per ounce troy, nominal	5	15	0
Zinc (Vicille Montague bud), per ton	27	10	0

Recent Metallurgical and Chemical Patents

Iron and Steel.

Basic Open-Hearth Process.—Mr. Louis M. Atha, of Newark, N. J., remarks that the ordinary basic open-hearth process of making steel from a mixture of pig iron, steel and iron scrap is expensive in certain localities owing to the high price of pig and the large amount of limestone necessary to add to the charge. The pig iron or cast iron are employed for the carbon they contain, to melt down the steel. Steel scrap could be substituted if carbon was introduced in some form separately. Mr. Atha states that while pulverized coke, charcoal or anthracite will not do, because they are carried off with the vapors, oil retort carbon may be advantageously employed. He uses 75 per cent steel scrap, 18 cast iron or pig iron, 2 carbon, and 5 limestone. "These proportions give a saving of about 30 per cent of pig and 50 per cent of limestone. By using steel scrap, which is low in phosphorus, it is not necessary to use as large a quantity of limestone as usual." (943,171, Dec. 14, 1909.)

Tool Steel.—Mr. John W. Evans, of Belleville, Ont., Can., patents, a tool steel, containing 92 per cent or more of iron, 3 per cent or less of titanium, 2 per cent or less of vanadium, 3 per cent of nickel or less, and 1 per cent or less of carbon. It has "the characteristics of being tough and hard to the end that it will retain an edge when working hard metals at high speed." (948,166, Feb. 1, 1910.)

Furnace Construction.—Details of construction of a special furnace for the heating of the ends of blanks from which bolts are to be manufactured are described in a patent of Mr. Edwin Alls. (943,763, Dec. 21, 1909; assigned to Monarch Engineering and Mfg. Co.)

Electric Steel.—Three new modifications of induction furnace designs for steel refining, due to Gronwall, Lindblad, and Stalhane, Unger and Grunwald are described below under Electrical Furnaces. At the same place will be found a method of Queneau of using the pinch effect for mixing an electric furnace charge, and a method of Strauss of making calcium silicide for steel refining.

Copper.

Fractional Roasting and Flotation Process.—To separate the valuable metals from such ores as chalcopyrite $CuFeS_2$, bornite or cruhesite Cu_3FeS_3 and mixtures of the same with pyrites in which copper is chemically combined with iron, Mr. A. S. Ramage, of Newark, N. J., subjects them to a fractional roasting process, with subsequent separation by flotation. For instance, in case of an ore containing iron pyrites and chalcopyrite, with a content of about 5 per cent of copper and from 30 to 40 per cent of sulphur, the ore is roasted at about a red heat in a furnace capable of utilizing the exothermic reaction between the ingredients of the ore. The roasting is conducted at a temperature sufficient to decompose only the iron sulphide, and leave the copper in the form of copper sulphide. The roasted ore is then crushed to at least fifteen mesh and passed through a solution of acid sulphate of soda and free nitric acid (the solution being formed by adding nitric acid to sulphate of soda), which solution is kept near the boiling point. The copper sulphide immediately rises to the top of the bath and can be floated off. Any copper oxide which may have been formed in the roasting operation, at once dissolves and can be recovered from the solution by any of the well-known ways.

Where the ore contains besides iron pyrites and chalcopyrite, zinc blende in quantity, the ore is roasted at a temperature of not over 600° C, with the result that the iron sulphide only is decomposed. The roasted ore is then subjected to the acid sulphate of soda solution in the manner before described, the solution being kept at nearly the boiling point, when the unchanged sulphide of zinc and copper rise to the top of the bath and are floated off, thus being together separated from the iron oxide. The copper and zinc sulphides are then roasted at about 700° C, until all the zinc sulphide is decomposed, the burnt mixture, after cooling, being treated with dilute sulphuric acid, whereby the zinc is completely dissolved, and the copper sulphide is left unchanged. The zinc may then be recovered from the solution by electrolysis in any preferred manner.

In the case of the ores of the Cobalt district, Dominion of Canada, which are principally cobalite, nicolite, and mixtures of chalcopyrite and pyrites containing silver in the metallic state and also as sulphide and sulpharsenide, these minerals are "floated" from the gangue, the metallic silver remaining with it, and from which it is mechanically separated. The sulphides and sulpharsenides of cobalt, nickel, iron and copper are then roasted at about 800° C, the roasted ore is "floated" as above and the copper sulphide floated off. The iron, nickel, and cobalt are reduced together as an alloy, electrolytically. (949,002, Feb. 15, 1910, assigned to Chemical Development Co.)

Reduction of Copper Sulphide.—The nearly pure sulphide

of copper obtained in the above process is placed by Mr. Ramage in a cylindrical furnace, where it is reduced to the metallic state by mixture of hydrogen and water gas at a low red heat. At this temperature the hydrogen reduces the copper sulphide to metallic copper in the form of a powder, while the carbonic oxide and sulphuretted hydrogen gases pass off and are led under and around the cylindrical furnace and burned to supply the heat necessary for reduction. The reduced metallic powder is delivered from the furnace into air-tight chambers and allowed to cool. The ore could be reduced by means of carbon, but some undecomposed carbon always remains, and in the subsequent electrolysis contaminates the electrolytic copper, so that the gaseous reduction is preferable. The cold metallic powder is preferably then used as an anode in a suitable electrolyte. The cathodes can be sheets of copper or revolving tubes. (949,003, Feb. 15, 1910.)

Wet Process for Pyritic Copper and Copper-Nickel Ores.—Mr. J. T. Carrick, of Johannesburgh, Transvaal, digests the hot desulphurized crushed ore with an excess of hydrochloric acid, in the absence of oxygen, until the iron and also the nickel are dissolved out. (By treatment of the digester liquor with ammonia and aspiration of air through it, the iron is precipitated, and after removal of the iron precipitate, the nickel is thrown down by the addition of lime.) The ore remaining in the treatment vat after removal of the iron and nickel consists of a porous mass of gangue and sulphuric acid and by injection of compressed air the sulphide is oxidized to cupric sulphate, which is leached out in about 24 hours. (947,789, Feb. 1.)

Separation of Copper from Other Metals.—See below the abstracts of the patent of Chalas on copper-nickel separation under Electrolytic Processes and of the patent of Chance on treating copper-iron matte under Electrolytic Furnaces.

Gold and Silver.

Agitating Ore Pulp.—In the treatment of ore pulp there is a difficulty in preventing the heavier particles from settling to the bottom of the tank, where they would be practically withdrawn from the effective action of the cyanide solution. To prevent this, Mr. Bernard MacDonald, of Guanajuato, Mexico, employs the apparatus shown in Fig. 1, which makes use principally of compressed air, without the employment of mechanical stirrers and agitators. The charge is supplied to the tank from the overhead main *a* into the funnel *d* at the top of the charge pipe *e'*. The funnel *d* has a perforated bottom *d'* upon which rests the cyanide to be brought into solution. At its lower end the tank is subdivided into several compartments by transverse partitioning with inclined sides. In the illustration (in which the lower diagram is a horizontal section along the line 2-2 of the upper diagram), this partitioning is in form of a single ridge-like gable *i*, so that in this case there are only two compartments. In this case the charge pipe *e'* rests upon the summit of the gable *i*, and at one end thereof, and from this point it extends downwards and forwards, terminating in branch jets *h* directed toward the valve casings *j*. The charge pipe *e'* has a height of 40 to 47 feet, so that the hydrostatic pressure is strong enough to insure a vigorous exit of the charge from the jet openings. After the charge of ore pulp or slime has been supplied to the tank, or at intervals during such supply, the valve *f* at the top of the charge pipe is closed so as to cut off further supply of pulp, and through the pipe *g* (right below this valve) compressed air is admitted into the charge pipe *e'* to agitate the charge and prevent settling. Air-injector jets extend upwardly through the bottom of the tank into the valve casings *j*; they are connected with the supply of compressed air through the piping *p*. Right above the valve casings *j* are provided vertical transfer pipes *k*. By the action of the compressed air the heavy particles of pulp which tend to settle down in the pockets at the bottom, are driven up into the transfer pipes *k*, and are discharged again into the tank at the top through the T-connections *o*. In this way the whole pulp is continually stirred up and is being kept in a practically homogeneous consistency. After the treatment is completed, the pulp is discharged through the down-takes *g'* and pipe *g* at the bottom to the filter press. (948,766, Feb. 8, 1910.)

Electrolytic Amalgamation.—See the abstract of the patent of Alling below, under Electrolytic Processes.

Zinc.

Reduction by Carbon Monoxide.—A process for reducing zinc oxide to metallic zinc by carbon monoxide, practically pure and free from nitrogen, is patented by Mr. Oscar Loiseau, of Selaigneaux, Belgium. The carbon monoxide gas is produced at a temperature somewhat above the reduction

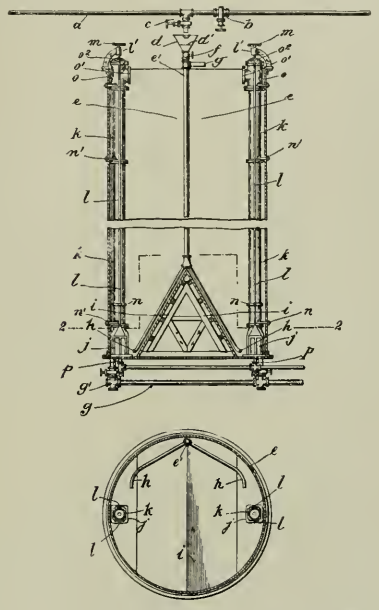

FIG. 1.—AGITATION OF PULP IN CYANIDE TANK.

temperature of zinc oxide (1400° C). The simplest way to produce the carbon monoxide gas is to have an incandescent mixture of coke and zinc oxide in a large closed reduction chamber and to blow pure oxygen, mixed with pure carbonic acid (free from nitrogen), over this mixture. The less the proportion of carbonic oxide compared with the oxygen, the higher is the temperature of the carbon monoxide gas produced. The reduction of the ore occurs according to the usual reactions; the role of the reducing carbon in the mixture is to transform immediately into carbon monoxide the carbonic acid derived from the reduction of the ore. The metallic zinc is obtained in separate condensers. The chief advantage of such a process would be the employment of a large-unit reduction chamber instead of the many retorts in present zinc smelting practice. The method is especially interesting as another indication of the great interest now being taken by various metallurgists in Belgium in the use of liquid air for the separation of oxygen and nitrogen, and the uses of pure oxygen for various metallurgical purposes. (947,831, Feb. 1, 1910.)

Electric Zinc Smelting.—A note in the abstract of a patent of Queneau on using the pinch effect for agitating an electric furnace charge, found below under Electric Furnace, refers to electric zinc smelting.

Various Metallurgical Patents.

Combined Roasting and Smelting Furnace.—Much has been heard last year of the Fink furnace, on account of the trial which it has undergone at Garfield, Utah, as described in

our Vol. 7, page 287. A patent of the inventor, Dr. Edward Fink, of Milwaukee, Wis., describes the furnace as follows: It is a combination of a heating or roasting barrel *a* and a smelting barrel *b*, which are arranged one above the other. Both barrels are charged with pulverized ore and fluxes and are rotated, the openings *i* of the barrel *a* and the tap holes 3 and 5 of the barrel *b* being closed. Fuel and air are supplied to the burner nozzles *q*, while air is blown through the pipe *s* so as to direct the hot blast over the ore in the smelting barrel *b*. By the rotation of the two barrels, the ore and the fluxes are thoroughly mixed and under the action of the hot blast in the lower barrel *b* the ore in it gradually begins to melt; the gaseous products of combustion escape through the flue *f* into the barrel *a*, where they heat the ore contained in it and finally escape through the flue *g*. The ore in the barrel *a* is thus gradually heated, and if it contains considerable sulphur this is ignited and the ore begins to roast; air being supplied thereto if necessary through the connection 6. The air blown through the tube *s* is heated so that a true hot blast is issued from nozzle *q*. When the smelting operation in barrel *b* is concluded the slag and the molten metal are withdrawn and by means of the connection *o* and the screw conveyor *n* the roasted ore from the barrel *a* is now brought into the melting barrel *b*. Then the conveyor is again removed from the hole *m* and the latter is closed. Fresh ore is filled into *a* and the operation starts again. For converting or refining operations, as, for example, for converting matte produced from copper ores containing considerable sulphur into an enriched matte or blister copper, one or more twyers *w* are introduced into the barrel *b* and are connected with the blast pipe *z* of the blower *z*. Each twyer is adjusted so that its inner end will project slightly below the surface of the molten

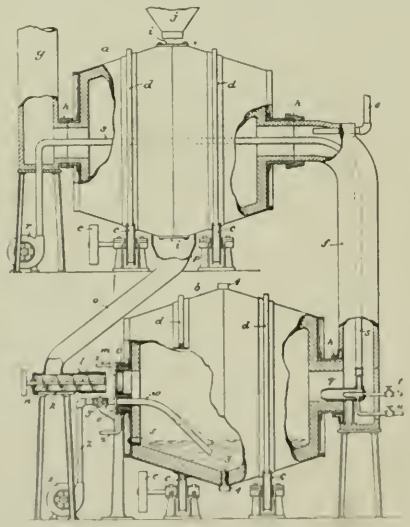

FIG. 2.—COMBINED ROASTING AND SMELTING FURNACE.

matte. Air is then blown and the barrel is rotated and a strong oxidizing flame is projected from the nozzle *q* over the matte. (948,468, Feb. 8, 1910.)

Nickel-Cobalt-Silver-Arsenic Ores.—For the smelting of ores which contain, besides silver, considerable quantities of nickel, cobalt, and especially arsenic (for instance, 300 to 10,000 ounces of silver per ton, to to 30 per cent nickel and cobalt, 5 to 40 per cent arsenic, no lead). Mr. C. C. Cito, of Irvington, N. J., proposes to add to the ore a percentage of copper, preferably equal to two-thirds of that of nickel and cobalt, and at least the same as that of arsenic, and not less in amount than the silver. The smelting operation, yields, firstly, an alloy containing besides copper, all the silver, nickel, and cobalt, and nearly all the arsenic in the ore treated, and secondly, a slag containing a very low percentage of silver, nickel, and cobalt. The alloy is subsequently separated by electrolysis, while the slag is used as flux in the blast furnace to recover the balance of the metals. (949,059 and 949,261, Feb. 15, 1910.)

Gas-Fired Vertical Smelting Furnace.—Mr. John S. Loder, of Reno, Nevada, builds the upper section of his smelting furnace in the usual way with vertical refractory walls. Below the straight vertical upper section is placed a funnel-shaped lower section made of metal and water-cooled, and this section is provided with a projecting shoulder or bulge. The ore charged into the upper section strikes the inclined lower section and the projecting shoulder, and the intention is to support it in this way in form of an arch by the high pressure produced below the shoulder by the gaseous fuel and air charged into the furnace through burners. This is intended to provide a free combustion space in the bottom of the furnace immediately beneath the ore, so that the flame plays on the bottom of the ore, gradually melting the same, which falls to the floor. (948,098, Feb. 1, 1910.)

Utilization of Flue Dust from Smelters.—Mr. N. H. Livington, of Globe, Arizona, proposes to utilize the collected flue dust from smelters directly in a converter without first briquetting it. The dust delivered from a hopper is blown into a pipe connected to a high-pressure blower and is then blown into a large pipe connected to a low-pressure blower and discharging into the converter, where the dust mixes with the molten metal. (943,752, Dec. 21, 1909.)

Electric Furnaces.

Induction Furnace.—To reduce or eliminate the primary stray flux (which has such a detrimental effect on the power-factor of an induction furnace), Messrs. E. A. Grönwall, A. R. Lindblad and O. Stalhane, of Ludvika, Sweden, place auxiliary coils in the path of the leakage flux in such a way that the magnetic flux produced by these coils counteracts the leakage flux. Fig. 3 shows one possible method. The coil 5 with the terminals 6 and 7 is the primary. The channel 4 containing the fused bath is the secondary. The coils 8 and 9 are the auxiliary coils; in the upper diagram one terminal 10 of one coil is connected to one terminal 11 of the other; the two other terminals 12 and 13 are connected to an outside source of current. If there exists primary leakage a greater number of lines of magnetic flux pass through leg 1 than through leg 2; the e.m.f. is induced in coil 8 is greater than the e.m.f. induced in coil 9. The difference of these two e.m.fs. is proportioned to the primary leakage flux. If a suitable current is passed through the coils 8 and 9 so that the m.m.f. of the coils will equal the m.m.f. with which the primary leakage flux tends to issue from core, the primary leakage is thereby overcome. Only a small voltage is then required at the terminals 12 and 13 of the coils 8 and 9, sufficient to overcome their ohmic resistance. The current for the auxiliary coils may be taken from the primary mains, and for this purpose the "Hick transformer coupling" may be employed; this is illustrated in the lower diagram. (942,961, Dec. 14, 1909.)

Silicon Carbide, Artificial Gems.—The theoretical reaction on which the manufacture of carborundum is usually based is $SiO_2 + 3C = SiC + 2CO$, and the following proportions by weight (affording a slight excess of carbon over that theoretically required) are used in practice: 35.1 per cent ground coke, 54.4 sand, 7 sawdust, 3.5 common salt. The silicon carbide thus produced occurs in the form of opaque crystals of various colors, the black predominating. Mr. Frank J. Tone, superintendent of the Carborundum Company, has discovered another reaction $3Si + 2CO = 2SiC + SiO_2$. This

is a gaseous reaction, gaseous silicon combining with carbon monoxide at a temperature below the temperature of dissociation of silicon carbide. The silicon carbide thus produced builds up in large crystals, which start upon crystals, initially

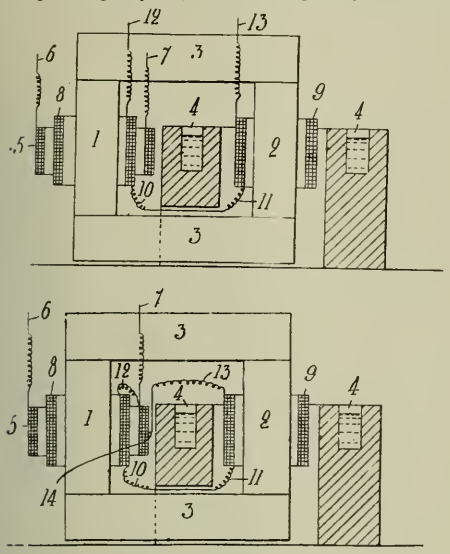

FIG. 3.—INDUCTION FURNACE.

formed by the direct union of silica and carbon of the charge, and by prolonging the operation of the furnace these crystals can be made to attain a large size. For this purpose the charge mixture should be constituted so as to afford spaces for the mingling and combining of the gases. This space is afforded by using sawdust in the charge mixture, preferably in a larger percentage than heretofore employed. Mr. Tone uses a carborundum furnace with a core of carbon, preferably in the form of carbon granules, free from contamination of metallic oxides (for instance, a carbon core taken from previous runs of a furnace). This he surrounds with a mixture of pure silica, petroleum coke (or purified ground coke), and sawdust. These are mixed in a proportion so that the silica will be somewhat in excess of the amount theoretically required by the formula

$$SiO_2 + 3\,C = SiC + 2\,CO.$$

These proportions by weight are attained by the following mixture: ground carbon, 30 per cent; silica, 57 per cent; sawdust, 9 per cent; common salt, 4 per cent. The furnace is then started and the operation is carried on for such a length of time that the zone of carborundum crystals adjacent to the core is decomposed to a considerable thickness, preferably to an extent of 2 in. or 3 in. The decomposition of these crystals results in the liberation of silicon vapor, which combines with the carbon monoxide gases in the furnace and builds up large crystals of carborundum just outside the zone of graphite which is formed by the decomposition. The crystals thus produced are clear and transparent, being free from coloration, and can be made of a large size. It is important that the carbon of the charge should not be in excess, since otherwise the crystals produced are apt to be black. These crystals have a very high index of refraction (exceeding that of crown glass and the diamond) and possess double refraction and are stated to be of great value as gems, since they can be cut with regular facets and polished. By adding to the furnace charge a small amount (not more than 0.5 per cent) of a coloring material, like oxide of chromium or oxide of manganese, the crystals can be tinted without destroying their transparency. (949,386, Feb. 15, 1910; assigned to Carborundum Company.)

Induction Furnace.—A modified form of induction furnace has been devised by Mr. MAGNUS UNGER, of Pittsfield, Mass. Fig. 4 shows it in perspective, with a plan view with connections to a polyphase system. It is a tilting furnace with two sets of primary windings 3 and 4 wound upon cores 5 and 6. Surrounding the primary windings is the furnace chamber 7. The annular furnace chambers interlink to form a central space which is used as a convenient treating chamber. As the annular channels surrounding the primary cores may be made of comparatively small cross-section without sacrificing the capacity of the furnace, the resistance at these regions will be correspondingly high, thus keeping a high power-factor and at the same time making a furnace of larger capacity than it is otherwise possible to operate with commercial frequencies. As there will be practically no current in the center of the furnace, the furnace chamber is made shallower at this point by the projection 9. However, the central chamber holds a considerable amount of the charge, which is protected in this way from excessive radiation, and the furnace has, therefore, a high thermal efficiency. The central space may be used for the introduction of comparatively large blocks of raw material, either ore or flux. The furnace may obviously be operated also by single-phase current. The design reminds one somewhat of the general arrangement of the Roechling-Rodenhauser furnace, although the pole plates characteristic for the latter are absent. (941,435, Nov. 30, 1909; assigned to General Electric Company.)

Induction Furnace.—To prevent the radiation of heat from the open top of an induction furnace and to permit the charging of the furnace when closed while facilitating full inspection of its interior, Mr. CARL GRUNWALD, of Essen, Germany, builds the secondary melting channel of oval or rhombic rather than circular form and provides it with lateral charging doors so that it is possible to inspect the entire surface of the

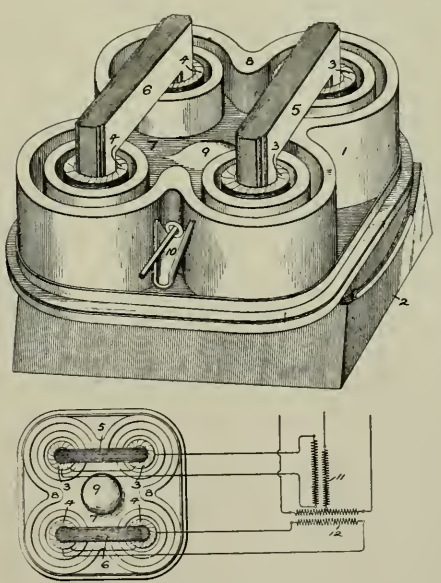

FIG. 4.—INDUCTION FURNACE.

molten charge from these two ends. (943,403, Dec. 14, 1909.)

Mixing of an Electric Furnace Charge by Pinch Effect.—Mr. A. L. QUENEAU, of Philadelphia, Pa., makes use of the "pinch effect" to produce regular pulsations in an electric furnace charge in order to thoroughly mix it. His arrangement, as applied to a three-phase furnace, is illustrated in Fig. 5, only two of the electrodes *i* being shown. The description relates

to steel refining. In this case the electrodes *i* are made of steel and are inserted in the lower ends of three narrow channels which converge upward and connect with the molten charge in the hearth *c*. With a sufficient current the pinch effect manifests itself in the channels *g*, near the upper end, a short distance below the entrance to the hearth, and will thereby cause an interruption of the molten-metal column within the channel. But the hydrostatic pressure of the heavy metal bath in the hearth will immediately close again this disruption, then it is broken again, and so on. It is emphasized that the interruptions occur at places where reducing conditions prevail so that there can be no oxidation of the disrupted surfaces. These pulsations are transferred to the molten metal in the hearth which is thereby held in constant agitation and thoroughly mixed. While the description in the patent specification relates primarily to steel refining, Mr. Queneau, who is a well-known authority on zinc metallurgy, thinks that the furnace would also be suitable with a molten metal as resistor, which is not to be refined itself, but is used as a source of heat to transmit the

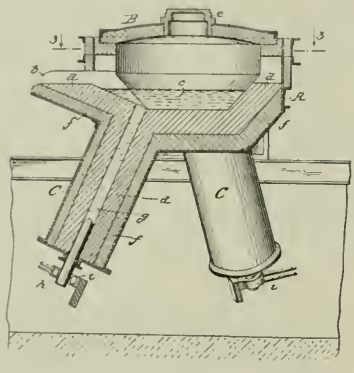

FIG. 5.—MIXING CHARGE BY PINCH EFFECT.

heating effect "to a charge of some other material superposed upon it, as, for instance, a zinc ore charge made up of the usual mixture of zinc ore and coke for the production of spelter." (948,343, Feb. 8, 1910.)

Electric Furnace for Reduction of Scruff and Dross.—Mr. Raymond S. Wile, of Pittsburgh, Pa., uses the furnace shown in Fig. 6 for the reduction of scruff and dross from tinning, galvanizing and similar operations. The metal shell 2 is lined with the refractory 3. Of the two carbon electrodes 6 and 7 the upper is movable. The dross or scruff, mixed with coke dust as reducing agent, is fed into the upper part of the furnace and rests on a bath of neutral melted material, such as glass. The upper electrode is so suspended that it just dips into the surface of the melted glass bath. The object of the melted glass bath is to collect in it the reduced metal, which is thereby protected against oxidation. The metal collects around the lower electrode and is tapped out from time to time. One chief advantage of this furnace is that the loss of metal which occurs in present methods is practically eliminated. Any metal or metallic oxides which may be volatilized in the lower portions of the charge is condensed again in the upper portions. The molten bath of glass must, of course, be of lower specific gravity than the reduced metal. (947,723, Jan. 25, 1910, assigned to American Sheet & Tin Plate Company.)

Calcium Silicide for Steel Refining.—The production of calcium silicide, which is now finding more and more extended use in steel works, is the subject of a patent of Mr Georges Strauss (assigned to Societe Anonyme La Compagnie Generale d'Electro-Chimie de Bozel, of Paris, France). By heating a mixture, in definite proportions, of lime, silica and carbon in an electric furnace, calcium silicide is obtained according to the equation

$$CaO + 2\,SiO_2 + 5\,C = CaSi_2 + 5\,CO.$$

But the direct formation of silicates is a troublesome element in this process. To avoid this, Strauss uses calcium carbide (instead of lime) and metallic silicon (instead of silica) as

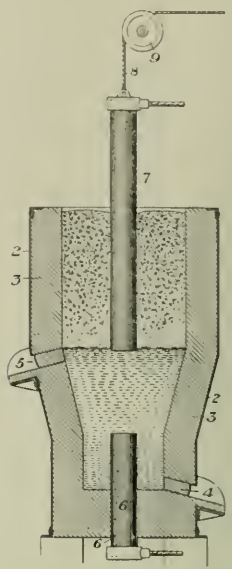

FIG. 6.—FURNACE FOR REDUCTION OF DROSS.

starting materials. He gives the following equations for the reactions:

$$CaC_2 + 2\,SiO_2 + 2\,C = CaSi_2 + 4\,CO.$$
$$2\,Si + CaO + C = CaSi_2 + CO.$$

"Experiments made with calcium silicide have shown that this metallic silicide is capable of replacing with advantage the aluminium usually employed in steel works for the purpose of preventing the formation of blow holes in steel ingots. The advantages ensuing from such application are, in addition to the economy secured by the very low price of calcium silicide, very great rapidity of reaction and the suppression of the undesirable 'shortness' which aluminium communicates to ingots of steel." (948,190, Feb. 1, 1910.)

Refining Tantalum.—While heretofore tantalum (for the manufacture of lamp filaments) has been chiefly refined by electric furnace methods, Dr. E. Weintraub, of the General Electric Company, has devised an electrolytic process for refining tantalum. A molten solution of potassium-tantalum fluoride is electrolyzed between an anode of impure tantalum and a cathode of pure tantalum or of other conductive and inert material. The impurities in the anode (carbon, tantalum, oxide, etc.) fall to the bottom of the cell. (947,983, Feb. 1, 1910.)

Electrolytic Furnaces.

Separation of Metals From Mattes or Speisses.—Messrs. E. M. Chance, of Philadelphia, and E. Kent, of Lansdowne, Pa., use the matte or speisse infused form as anode in an electrolytic furnace. The metal to be separated passes into the fused electrolyte and is deposited on the cathode. For instance, if lead, containing 2 per cent to 5 per cent of silver, is to be treated, it is molten and used as anode with a fused electrolyte of double silicate of lead and sodium. The lead passes into the electrolyte and is recovered at the cathode, while the silver re-

mains back at the anode. A second example is the treatment of copper-iron matte with fused sodium and potassium silicate as electrolyte (which may with advantage contain about 2 per cent of manganese sesquioxide to increase fluidity). If the e.m.f. is maintained below a certain critical value, only the copper is dissolved in the electrolyte and deposited on the cathode. (948,681, Feb. 8, 1910.)

Electrolytic Processes.

Electrolytic Amalgamation.—Gold in such a finely divided state that it cannot be recovered by ordinary methods is recovered by an electrolytic amalgamation process of Mr. James H. Alling, of San Francisco, in the apparatus shown in Fig. 7 in plan view, the lower diagram being a broken side view of part of it. 1 is the sluice box, which is sloped at a greater angle than usual sluice boxes. Its bottom contains a continuous amalgamating plate 2, formed at intervals into pockets or troughs 3. Each pocket has a rear wall 4 with considerable slope, a front wall 5 sloping slightly backward, and a bottom substantially horizontal. In each pocket is a quantity of mercury 7. The sides of the sluice box are formed with oblique grooves 8 inclined rearwardly upward, and across the sluice box extend amalgamating plates 9 with their edges in said grooves. These are made anodes. In addition to them there are provided swinging carbon anodes 16 suspended from bars 17 extending across between the tops of the sides of the sluice box, substantially midway between the anode plates 9. The amalgamating plate 2 in the bottom is made the cathode. The material, having been first finely pulverized is fed by a chute 23 into the top

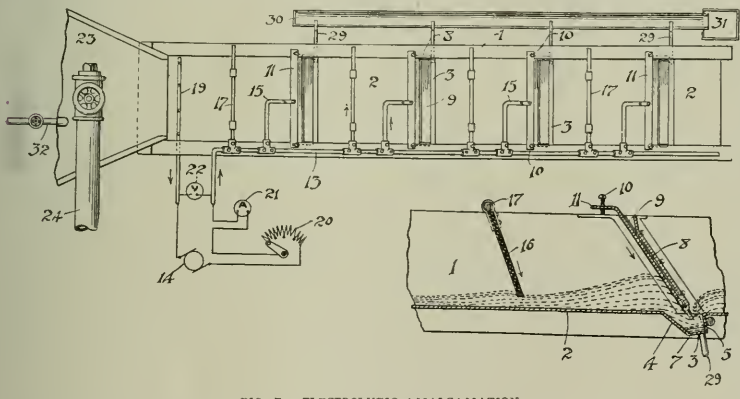

FIG. 7.—ELECTROLYTIC AMALGAMATION.

of the sluice box. At the same time there is fed, by a pipe 24, a sufficient quantity of water, about four tons to 1 ton of material, and through a pipe 32 is fed a small proportion, about 1 to 1000, 2000 or more parts of a mixture consisting of aqueous solutions of potassic cyanides and mercuric chloride. The proportion of the mixture to the water will vary according to the richness of the material being treated, the rule being to supply in the mercuric chloride 1 oz. of mercury to each ounce of gold in the material. In treating certain ores the inventor has found satisfactory proportions by weight to be ½ lb. to 1 lb. of potassic cyanide to 2 oz. mercuric chloride and 5 gal. of the solutions. The addition of the cyanide facilitates the electrolysis and cleans the gold. The density of the current used is comparatively low, being from 1/10 amp to 1 amp for each square foot of cathode surface according to the richness of the material. A tension of about 5 volts is used. It is in order to replenish the aqueous solution of mercuric chloride with mercury that the surface of the anode is amalgamated and since the mercury is continually being removed from the rear surface of the anode plates by electrolysis, as well as by the impact of the particles of gold, it is desirable to replace this mercury as fast as removed, so that there will always be a sufficient coating of mercury upon the anode plates to obtain a proper action of the apparatus. The inventor states that he has been able to save "over 95 per cent of the values of material containing finely divided gold, which cannot be saved by ordinary means." The principal advantages of the system of electrolytic amalgamation over the ordinary cyanide treatment are stated to be the saving in cost of plant and time and labor required in the process. (947,957 and 947,958, Feb. 1, 1910.)

Nickel-Copper Separation.—The old problem of separating the nickel and copper from the nickel-copper-iron sulphide ores of the Sudbury district, which has attracted so many inventors, is the subject of a patent of Dr. Adolphe Chalas, of Philadelphia, Pa. The nickel-copper matte from pyrrhotite smelting is bessemerized to slag off the iron and to concentrate the nickel-copper contents to about 80 per cent. The resulting rich matte is then roasted to convert it into oxides of nickel and copper, which are finally reduced, with production of an alloy of nickel and copper. The resulting nickel-copper alloy is then cast into anodes, which are placed in an electrolytic cell, No. 1, having sheet cathodes of nickel, copper, or iron, and containing as an electrolyte an aqueous solution of an alkali-metal salt, for example, sodium chloride. The anodic and cathodic solutions are separated by a diaphragm. As electrolysis proceeds, nickel and copper are dissolved from the anodes as chlorides, while a sodium hydroxide solution is produced at the cathode. During electrolysis the solution is continuously circulated from the anodic compartment of the cell through a filter, No. 1, containing a body of precipitated nickelous (cuprous) hydroxide, which reacts upon the dissolved copper chloride with production of dissolved nickel chloride and precipitation of copper hydroxide.

The solution thus freed from copper and containing an additional amount of nickel equivalent to the removed copper is mixed with the alkali solution which continuously flows from the cathodic compartment of the cell. These two solutions when mixed react with the production of pure nickelous hydroxide, which precipitates, and sodium chloride brine. The brine, carrying the precipitate in suspension, is circulated through a filter, No. 2, which retains the pure nickelous hydroxide, the clear solution being returned to the cell to regenerate the electrolyte. When the nickel hydroxide in filter No. 1 has been completely dissolved and replaced by precipitated copper hydroxide, the stream of electrolyte from the anodic compartment of cell No. 1 is diverted to a filter, No. 3, which has been filled with fresh precipitated nickelous (cuprous) hydroxide, and the first filter is emptied, cleaned and refilled. When filter No. 2 has also been filled with pure nickel hydroxide it is also replaced by another and is emptied and cleaned for subsequent use. The pure copper hydroxide from filter No. 1 and the pure nickel hydroxide from filter No. 2 may be merely dried or calcined to give pure copper and nickel oxides. The nickelous (cuprous) hydroxide used in filter No. 1 for the precipitation of copper is produced by directly mixing the anodic and cathodic solutions flowing from an electrolytic cell, No. 2, identical with cell No. 1, so that nickel and copper hydroxides precipitate together. The brine, carrying the precipitate in suspension, is circulated through a filter, No. 3, which retains the mixed hydroxides, the clear solution being returned to cell No. 2 to regenerate the electrolyte. The nickelous hydroxide alone reacts with the anodic solution from cell 1.

Commercially five filters or sets of filters are preferably employed, which are worked in rotation; filter No. 1 containing nickel-copper hydroxide is used in the second stage of the process, while filter No. 2 is being filled with nickel hydroxide free from copper, and filter No. 3 is being filled with nickel-copper hydroxide. Filter No. 3 is then substituted for filter No. 1, an empty filter; No. 4 is used to replace No. 2, and the last filter, No. 5, is filled with nickel-copper hydroxide in sequence with No. 3, the process being cyclic and the reagents continuously regenerated. (947,791, Feb. 1, 1910.)

Electrode Construction.—Mr. John William Stubbs of Middlewich, England, patents the electrode construction of Fig. 8, showing sectional views at right angles to each other. Between a pair of copper bars *a* are disposed at intervals the cross-bars or nipples *c* of carbon. Lead *b* is then cast around the carbon nipples and between them and the copper bars *a*, thus attaching the carbon nipples firmly to the conductor bars, both mechanically and electrically. The copper bars are then coated with tar, pitch, paraffin wax, asbestos impregnated with oil, or some other impervious insulating material to prevent corrosion of the copper by the electrolyte, and are finally covered with Portland cement *g*. The ends of the carbon nipples are furnished with carbon blocks *h*. The electrodes are evidently intended for sodium chloride electrolysis. (947,358, Jan. 25, 1910.)

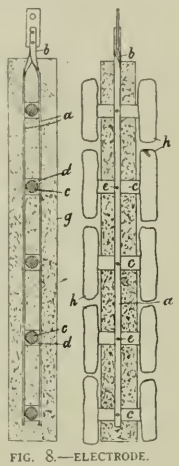

FIG. 8.—ELECTRODE.

Charging Device for Electric Furnaces.—The construction described and illustrated by Taussig on page 46 of our January issue, is covered by a recent patent of A. Helfenstein. It relates especially to the broad openings or slots which are provided in the roof of the furnace around the charging hopper. These openings are usually tightly closed by sand-sealed covers, but they permit access to and guarding of the heating zone and entrance of the mixture in the electric melting hearth also during the charging period. They are useful for the removal of slag and crusts, for ascertaining any breaking of the electrode and for removal of the broken part. The openings permit also to introduce ingredients to correct the mixture, when disturbances occur which require an interruption of the working. They also act as safety valves in cases of too high gas pressure, avoiding so an escaping of gas through the high mixture pile in the charging pit and the charging tubes. By these slots the closed furnace possesses all advantages of an open furnace without the disadvantages of the same. For further details see Taussig's paper. (942,068, Dec. 7, 1909.)

Electric Discharges Through Gases.

Electric Furnace for Producing Nitric Acid from Air.—A peculiar furnace construction which has some points in common with that of Birkeland and Eyde, and also with that of the Badische Company, but differs essentially from both of them, has been patented by Mr. F. I. duPont (E. I. duPont de Nemours Powder Company). He uses a long tube of quartz with electrodes in both ends, between which the arc is formed. But this arc is not straight as in the furnace of the Badische Company, but is deflected and kept in rotation by means of various rotary magnetic fields. For this purpose a number of magnet systems are placed one above the other in such a way that in any system the polarities are reversed as compared with the adjacent magnet systems above and below. In this way the arc is caused to rotate and to be blown from side to side of the tube. The air, while flowing through the tube, has to pass through the arc as many times as the arc crosses over the tube, and between passages it is cooled by contact with the quartz tube, which is cooled from the outside. (943,661, Dec. 21, 1909.)

Synopsis of Metallurgical and Chemical Literature.

Sintering of Iron Ores.—Dr. J. Savelsberg, in German patent 210,742, makes an interesting proposition for the sinter-roasting or plain sintering of fine iron ores, manganese ores, pyrites, cinders, flue dust and other metallurgical materials. He mixes them with a small amount of waste fuel, and "hessemer" roasts them in the well-known Huntington-Heberlein converter, used so successfully for self-roasting of lead sulphide ores. The fuel may be coal dust, coke breeze, lignite, peat, waste wood, etc., and 8 to 15 per cent of the weight of the ore is sufficient for the sintering. The sinter roasting burns out the fuel and sinters the material together to cakes which may be broken into any desired size, and which are very well suited for blast furnace reduction. (*Métallurgie*, Oct. 8, 1909.)

Blast Furnace Slag for Cement Making.—In the Lond. *Elec. Review* of Feb. 11, a description is given of the use of the Colloseus process for utilizing the slag of the blast furnace in cement making at the Coltness Iron Company works at Newmains, Lanarkshire. This is the first plant of its kind in Great Britain. The blast-furnace gases are utilized for operating three gas engines, two of them being for blowing purposes and the third for generating electric power for operating the ball and tube mills, conveyors, etc., in the cement mill.

Rotary Extractor for Precious Metals.—In the December, 1909, issue of the *Journal* of the Chemical, Metallurgical and Mining Society of South Africa, W. D'Arcy Lloyd and Ernest T. Rand point out that from time to time attempts have been made to precipitate gold and silver from their cyanide solutions while the precipitating agent was in motion, with more or less success. For example, zinc shavings have frequently been subjected to mechanical motion while in contact with the gold and silver cyanide solutions and in most cases as far as actual precipitation of metals was concerned, some success has been achieved, but mechanical difficulties have developed due to the method of applying motion by attrition, etc. The main idea underlying all the attempts to perform the operation of precipitation with the precipitating agent in motion is to avoid the fouling of the zinc, which is so painfully evident in the first compartments of all extractor boxes after a three days' run from time of dressing. It is well known that after thorough washing and redressing, the zinc will go on precipitating as briskly as ever until fouling starts again. The natural inference from this is that if the zinc could be kept continuously in motion, thus preventing fouling, the highest efficiency would be maintained. With this point in view, the authors devised a rotary extractor machine, which will be described in greater detail in a later issue, and for which on the basis of the experiments the following advantages are claimed: (1) Ready access by authorized persons to the gold slimes, without stoppage of precipitation, enabling a daily clean up to be made if required. (2) With clippings and coarsely cut filiform zinc, absence of breaking down and readiness of removal of adhering gold in an acid bath without consumption of all the zinc, with a consequent saving of zinc and acid. (3) Clean-up quick and cleanly with a consequent advantage of a minimum of loss. (4) Shortness of time rotor is out of action during dressing. (5) No fouling of zinc. (6) While in operation no danger of theft of gold slimes, as all valves would be locked. In the discussion which followed Mr. A. F. Crosse pointed out another advantage, namely, the mechanical driving off of the hydrogen bubbles from the zinc, since this removal of hydrogen helps precipitation.

An Electrolytic Zinc Process.—For some time reports have

been received on a new electrolytic process of producing zinc from ores, in which the Siemens & Halske Company is interested. This has now been described by V. ENGELHARDT and M. HUTH in *Metallurgie* of Jan. 8. The authors emphasize that if an electrolytic zinc process shall be successful the process must be very simple and the apparatus cheap and durable. The main difficulty is to maintain the zinc salt solution always in good, pure condition, since when it is fouled the deposit of the zinc becomes spongy, and besides the zinc deposited on the cathode is redissolved by the free acid. Only as long as the zinc salt solution is kept in great purity, the redissolving of the deposited zinc by the solution can be prevented. The chief difficulty of keeping the solution pure when using a sulphate solution is the selection of a proper anode material. Platinum is out of the question on account of the cost. Carbon anodes are quickly destroyed, while from lead anodes or hard lead anodes such considerable quantities of lead pass into solution that the electrolytic zinc deposited on the cathodes becomes impure and loses its resistivity against the acid. The iron oxide solutions which have been found successful in sodium chloride electrolysis are also attacked by the sulphate solution and the deposition of pure zinc is no longer possible. The first anodes that were found successful for zinc sulphate electrolysis were the lead peroxide anodes of Ferchland. By the use of these anodes it is possible to obtain a pure zinc which is not attacked by the solution even if it contains as much as 10 per cent of free sulphuric acid. In an experimental plant in Upper Silesia sulphate electrolysis with Ferchland lead peroxide anodes was carried out on a larger scale for about a year. The process was found to be technically successful. The losses of zinc are three times greater with zinc smelting than with the electrolytic process. Further, the operation showed that the purification of the solution to the desired high degree could be carried out easily and without great cost if certain precautions were taken in the making up of the solutions. With the exception of some small troubles in the beginning, the electrolysis itself was quite successful. The electrolytic zinc has a purity of 99.98 per cent to 99.99 per cent. The energy consumption was 3.9 kw-hours per kilogram of zinc. This relatively high power consumption was due to the small mechanical durability of the anodes, causing both an increase of voltage and a reduction of amp-hour efficiency. With a more durable anode material the authors figure that the energy consumption would be 3.3 kw-hours to 3.5 kw-hours per kilogram of zinc. The cost of operation per 1000 kg of electrolytic zinc was $39.25. This figure includes cost of power (0.625 cent per kw-hour), wages, material for purification of solution, remelting the electrolytic zinc, general cost, and license. But the figure does not include amortization or cost of ore. Two-thirds of the figure of $39.25 is the cost of electrical energy, so that the authors think that with very cheap power the production of 1000 kg of electrolytic zinc could be reduced to about $19.25. (Under the condition of power cost in this country this would hardly be possible, since a cost of 0.625 cent per kw-hour is already very low.) An equally excellent material for anodes for sulphate electrolysis, to be used as a substitute for the lead peroxide anodes of Ferchland, are the manganese peroxide anodes made by the process of Siemens and Halske. This material used as an anode in a sulphate solution is absolutely insoluble and is far more durable than lead peroxide anodes. Experiments made with manganese peroxide anodes for over a year have shown that these anodes will last for several years. While the Ferchland lead peroxide anodes can be made only in stick form, the manganese peroxide anodes can also be made in plate form. In spite of the comparatively successful results obtained in the plant in Upper Silesia, the process has not been introduced on a large scale. The reason is stated to be that the electrolytic process when carried out with steam power and when treating expensive high-percentage ores is economical only if the very pure electrolytic zinc will demand a considerably higher price than the commercial spelter. At present there is a margin of $50 per ton for very pure zinc. But whether this margin could be maintained for very pure zinc produced on a large scale is doubtful and it would be injudicious to build a plant on the basis of such expectations. A small margin will, however, always be maintained since the cost of rolling is considerably lower with the pure zinc on account of its great softness. The authors expect, however, that the electrolytic process can be used safely with an expectation of profit in all cases in which poorer and cheaper ores or zinc scrap are to be treated

Protective Lime Diaphragm On Cathode; Production of Hypochlorites and Chlorates.—In the electrolysis of aqueous solutions for the reduction and oxidation of chemical compounds it is important to prevent the cathodic reduction products from being oxidized again by contact with the anode and to prevent the anodic oxidation products from being reduced again at the cathode. The old ordinary diaphragm cell has distinct disadvantages in many cases. A modification—in which a diaphragm close to and adhering to the cathode is produced automatically during electrolysis in the cell—has been found useful for the production of hypochlorite and chlorate. Thus H. Bischoff and F. Foerster found in the electrolysis of alkali chlorides for hypochlorite production that an addition of calcium chloride greatly diminishes the cathodic reduction of the hypochlorite formed; this is due to the formation of a layer of lime on the cathode which prevents direct contact between the hypochlorite and the cathode. E. Mueller has later shown that an addition of potassium chromate is even more effective; it results in the formation of a chromium oxide diaphragm which prevents any cathodic reduction whatever. The use of an addition of calcium chloride in the commercial manufacture of hypochlorite and chlorate has failed because the diaphragm formed at the cathode would not stick to it with sufficient rigidity. E. MÜLLER and M. BUCHNER have now found (*Zeit. f. Elektrochemie*, Feb. 1) that they can produce a firmly adhering lime diaphragm on the cathode by adding a very small quantity of a colloid (gelatine, etc.) to the solution to which calcium chloride or chromate has been added. This effect of the colloid seems to be the same as in the Betts lead refining process, where the application of a very small amount of a colloid results in a firm adhesive deposit of lead.

Ammonia-Soda Process.—A recent lecture by Prof. A. COLSON, of Paris, before the Society of Chem. Ind. in London is noticed in Lond. *Eng'ing*, Feb. 11. "Prof. Colson is manager of the St. Cobain Alkali Works, in which the ammonia-soda process is used. Professor Colson dealt in his lecture with the present state and possible modifications of the ammonia-soda process. The lecturer stated that the value of the soda produced by the process was about £2,000,000 annually: owing to the salt duty, France produced only $1,500,000 worth—less than England and Germany. Four operations might be distinguished: The decomposition of limestone into quicklime and carbon dioxide; the precipitation of sodium carbonate from ordinary salt solution by means of ammonia and carbonic acid; the calculation of the sodium bicarbonic to carbonate (soda): and the regeneration of ammonia from the chloride formed by means of caustic lime. The ammonia played an intermediate, though most important part. The total heat balance of the whole reactions was the evolution of 5200 calories, but 44,500 calories were required for decomposition of the limestone and coal was hardly required for the other reactions." There were many difficulties in the different operations more perhaps for the engineer than for the chemist, for the chemistry was well understood. For instance, the pumps drawing off the carbon dioxide were rapidly destroyed by the gas and the flue-dust. The precipitation of the bicarbonate had to be rapid lest a double carbonate of ammonium and sodium be formed or some ammonium chloride be precipitated with the carbonate; the latter would be destructive to the cal-

ening plant. The regeneration of the ammonia was now effected by quicklime, not by milk of lime, and the ammonia was absorbed by water. The operation took place in column apparatus, such as were used for the rectification of alcohol, but they were much larger, as volumes of 15 and 20 cubic meters had to be dealt with per hour. In one case gas discharge pipes of insufficient cross-section had caused very serious trouble. It was also most essential to secure actual contact between the lime and the ammonium chloride. In some French works solid salt was the raw material of the soda; in others brine was used, which was exclusively applied in England. The process as worked in various Solvay works was now considered almost perfect, especially after the introduction of machinery to replace manual labor; that, however, required large capital. More than 2.5 kilogrammes of ammonia should not be lost in the cycle of operations if the process were to pay. Professor Colson then explained that his various experiments had been conducted not so much with the object of improving the various operations as with the object of suppressing some of them. He proceeded to show how this could be done when sodium nitrate was substituted as raw material for the chloride (ordinary salt). The by-product would then be a mixture of sodium and calcium nitrates, which was as valuable almost to agriculture as the original Chili saltpeter. "The discussion of the paper was disappointing. One gentleman employed in the ammonia-soda industry said that he had almost been afraid that Professor Colson might give away some of the secret manipulations by which the troubles were overcome. One cannot help feeling that the discussions in our engineering and electrical societies, in which trade secrets used to be so jealously guarded, have of late years risen to a higher level."

Copper-Aluminium-Manganese Alloys.—The 8th report to the alloys research committee of the (Brit.) Inst. Mech. Eng., by Carpenter and Edwards, dealt with copper-aluminium alloys. This has now been followed by the ninth report, by W. Rosenhain and F. C. A. H. Lantsberry, of the Nat. Phys. Laboratory, on the effect which an addition of manganese has on the properties of copper-aluminium alloys. Broadly speaking, the ternary alloys, of which the principal ingredient is copper, when compared with the best binary alloys of copper and aluminium, present certain advantages, having a higher yield-point, a slightly higher ultimate stress, and undiminished ductility. The alloys were tested in the form of sand castings, chill castings and rolled bars. One alloy proved best in one form, while others surpassed it under other conditions. These alloys showed improvement in the rolled form over the chill-castings, especially in elongation. Certain alloys examined by dynamic test prove these particular ternary alloys to be practically equal to the binary alloy containing 10 per cent Al, but they show a very slight inferiority as regards the safe range of alternating stresses. On the other hand, under impact test some of the ternary alloys gave remarkable results—very remarkable ones, indeed—under the abrasion test in Dr. Stanton's machine. As regards corrosion in salt and fresh water, the ternary alloys are equal, and in some cases rather superior to the copper-aluminium series. With regard to the alloys at the light end of the series the results of the present investigation are not so favorable. In the case of one of the series the tests on chill-castings gave good tensile strength and elongation, but rolled bars of the same alloy showed no better results than those obtained with copper-aluminium alone. The temperature at which the metal is poured greatly influences the properties of these alloys. An almost complete reprint of this very long, illustrated report begins in Lond. *Engineering* Jan. 28.

A New Plating Method.—A new method of plating was described by Mr. A. Rosenberg in a recent lecture before the Society of Arts in London. (Lond. *Electric Review*, Feb. 11.) The desired metallic coating is produced by simply rubbing the surface with a paste made of a prepared powder. While the process is therefore simply one of rubbing the metal in, its principle is electrochemical. The rationale of Mr. Rosenberg's process is this: His plating powders are compounded of: First, some form (whether elementary or combined) of the metal to be deposited; secondly, an uncombined electropositive metal, usually magnesium, but sometimes aluminium, zinc or cadmium, in a highly divided state of division; thirdly, a substance capable of producing an aqueous electrolyte when brought into contact with moisture (this ingredient is only necessary when the metal to be deposited is present in the metallic state); and lastly, certain inert substances such as chalk, soapstone, kieselguhr, boracic acid, dextrine, etc., whose function is to act partly as diluents, to prevent premature too rapid action, and partly as polishing materials. It is clear that if a mixture of the above ingredients is moistened and rubbed over a clean metallic surface, an innumerable number of infinitesimal voltaic cells will be produced, and while the electropositive metal present—the magnesium, for example—will go into solution as anode, the metal of the salt present will be deposited on the surface under treatment, which acts as cathode, and as the paste is rapidly rubbed over the whole surface, a continuous metallic coating will be electrodeposited in the literal sense of the term. The following simple experiment may be made as an illustration. Rub a mixture of magnesium power (2 parts), and powdered nickel ammonium sulphate (20 parts) with a moist rag over a copper penny. This will immediately become coated with a bright film of nickel.

Further, to illustrate the reactions, take the mixture recommended for the deposition of zinc: Zinc dust, 15 parts; ammonium sulphate, 5 parts; magnesium, 1 part; chalk, 10 parts; soapstone, 2.5 parts. In this case it is advisable to use the zinc in the metallic form, and both magnesium and zinc will go into solution electrolytically forming their respective sulphates, while zinc will immediately be thrown out of solution again, as the action proceeds, and deposited on the cathode, namely, the object under treatment. The function of the soapstone in this instance is to prevent the mixture from absorbing moisture if exposed to the air. The chalk is useful both as diluent and as a polishing agent. It is further useful as a source of alkalinity, which, just as in ordinary plating, may be valuable in improving the color and quality of the deposit. The object to be plated has to be reasonably clean and free from grease, but the operation itself involves both mechanical and chemical cleaning, and hence the great precautions taken to clean the work in ordinary electroplating can be dispensed with in the new process. At the same time, the brighter and more highly polished the surface to be plated the brighter will be the deposit thrown down. The plating powders are being placed on the market under the name of "galvanit." At present only silver, nickel and tin mixtures can be obtained; but the list is to be extended, and will include alloys like brass and gun-metal, which, it is stated, can be plated with ease. It appears that the mixtures if kept in a fairly dry place do not deteriorate with time on account of local chemical action being set up; this is prevented partly by the presence of the inert substances referred to previously; and partly by coating the magnesium powder with a thin film of paraffin or resin, by immersing it in a volatile solution of these substances. The friction involved in the plating process is sufficient to remove the insulating films from the magnesium when that is no longer required.

Electrode Losses in Electric Furnaces.—In an appendix to his paper on electrode losses, just published in Vol. XVI. of the *Transactions* of the American Electrochemical Society, Mr Carl Hering gives the results of an experimental determination of his mean conductivities and resistivities between 100° C (cold electrode end temperature) and 900° C. (furnace temperature). In the inch units specified in his article in our last October issue they are: graphite $r = 0.000323$, $k = 0.740$; carbon $r = 0.00148$ and $k = 0.350$.

The Wood-Distilling Industry.

By Charles L. Campbell.

The rapid growth of the wood-distilling industry in this country from its start up to within the last two years, and recent developments in this industry in affecting it, taken together with the fact that there is no literature in the English language covering the subject to any extent, would seem to warrant at this time a brief review of the subject and a look at its future.

Historical.—The wood-distilling industry is a very old one, the subject being mentioned in the writings of the old Romans. The distillation was very crude, however, being carried on for the purpose of obtaining charcoal alone, and it was not until 1835 that any considerable advance was made in the industry. At this time Dumas and Poligot, in Europe, investigated the constitution of the vapors given off from the wood during distillation, and recognized the three principal constituents: acetone, methyl alcohol and acetic acid.

Other investigators examined the tar and gases formed, the gas, which usually contains about 30 per cent to 35 per cent of methane, CO, etc., being used by Lebon for lighting in some German towns. These investigations mark the beginning of the modern wood-distilling industry, although the first wood-distilling plant was started at Hausach, in Germany, in 1819, and a man named Adams established a plant at North Adams, Mass., in 1830, where the vapors constituting the pyroligneous acid were recovered.

The coal-tar industry in Europe, which began in 1856, at the time of Perkin's discoveries, marked the beginning of the modern epoch in wood distillation, since the production of coal-tar colors required the use of methyl alcohol and acetic acid and brought about the extensive refining of the pyroligneous acid after its recovery. This industry was, however, confined mostly to Europe, and the subsequent developments in organic chemistry, in which Germany was the leading factor, requiring the refined products of wood distillation, made her the center of this refining industry.

The industry in the United States, however, developed much more slowly, the first wood-alcohol refinery being founded in 1874 at Binghamton, N. Y., by G. C. Edwards. The industry in this country at that time was mostly for the purpose of producing charcoal for fuel or for making charcoal iron, in contrast to the German industry, where the refined products were the objective. It was, therefore, natural that the raw products of the industry in this country should be shipped to Germany, and such was the case, the record of import showing that in 1897 Germany imported an amount of raw materials from the wood-distilling industries equal to twice her production. This state of the two industries, American and German, has continued up to the present time, America exporting in 1908 one-third of its production of raw wood alcohol and large amounts of acetate of lime, but a change has been coming about and indications point to decreased exportation from and increased refining in this country.

Present Methods.—In order to understand where the industry in this country stands at present and the opportunities open to it in the future, a brief outline of the process used in the great majority of American plants will be given. In this country at the present time there are probably about 150 plants, ranging in size from 500 to 250,000 cords per day. In 1907 the following plants reported their yearly consumption and output to the Department of Agriculture:

States.	Number of plants.	Cords per year
Michigan	13	602,000 cords.
New York	28	127,000 "
Pennsylvania	53	358,000 "

However, while these three States support the majority of plants in the wood-distilling industry, yet there are many plants in other States which were not reported to the Department of Agriculture. This list also does not include the plants distilling pine woods for the purpose of obtaining oil of turpentine.

Of the processes used in these plants there are a great many modifications, and it would take a good-sized volume to discuss them all, but a thorough investigation has shown that of these special processes a majority have either failed entirely or worked unsatisfactorily.

There are two distinct processes in use at the present time, i.e., destructive and steam distillation, but the latter is a small industry as compared with the former and cannot be considered at this time. The destructive process in general use consists in heating the wood either by external heat or by partial combustion so that the wood-fiber material is broken down, the products yielded being:

(1) Charcoal.
(2) Tar.
(3) Watery distillate, pyroligneous acid.
(4) Uncondensable gases.

The object of the distillation is the recovery of one or all of these products, the amounts of same being dependent on the wood and the process used.

The destructive distillation process for which the principal kinds of wood used are beech, birch, maple and oak, and may be divided, in turn, into two distinct parts, the "kiln" and the "retort" processes. In the "kiln" process the primary object of the distillation is the production of charcoal, usually for making iron, and the center of this branch of the industry is in Michigan. The kiln is a bee-hive shaped brick retort, holding anywhere from 15 to 120 cords of wood, the kiln being packed by hand and heated by burning the wood with an insufficient supply of air, or by burning the uncondensable gases formed during the distillation, the kiln in this case being fitted with heating pipes in its interior and sometimes lined with metal. The time of distillation may be as much as three weeks, and the vapors which are given off are usually recovered.

In the "retort" process the object of the distillation is usually the recovery of charcoal and pyroligneous acid, as well as tar and gases. The retorts are made of iron, and are set in brickwork. They are of all shapes and sizes, the main types being:

(1) The small, upright, removable retort, packed by hand.

(2) The small, horizontal, cylindrical retort, fixed in position, and filled and emptied by hand.

(3) The large, horizontal, square or cylindrical retort or oven, fixed in position, and filled and emptied mechanically, the wood being in most cases packed on cars and these cars being wheeled into and out of these retorts.

Of these retorts type No. 1, the small, upright oven, is probably most used. These retorts may be heated by coal, wood or tar, or by the gases obtained in the distillation.

The vapors given off during the distillation are condensed by devices of some sort, various arrangements being made, but the main types are the coil, box and upright tubular condensers. The uncondensed gases are led by suitable pipes to be burned under the retorts without further treatment. The crude pyroligneous acid obtained contains approximately the following constituents:

Tar and tar oils	9.8 per cent.
Acetic acid	10.0 "
Methyl alcohol	3.0 "
Acetone	.2 "
Water	77.0 "

also propionic, valerianic and butyric acids, allyl alcohol, aldehyde, furfurol, ammonia, methyl acetate, methyl-ethyl ketone, amines, and pyridine bases, etc.

Further processes have to do with the removal of the various products from each other, and conversion into a commercial form. The tar and oils are removed for the most part by allowing the crude pyroligneous acid to settle, by which operation three distinct layers are formed, the lower one con-

sisting of tar with creosote oil and some pyroligneous acid; above that the pyroligneous acid containing considerable amounts of dissolved tar; and on top the lighter hydro-carbon oils.

By a proper arrangement of taps these different layers can be separated from each other and collected in separate tanks ready for subsequent operations.

The tar-containing pyroligneous acid is re-distilled in a steam-jacketed or coil-heated pan, by which operation the tar is left as a residue and vapors containing acetone, wood alcohol, acetic acid, water, and slight amounts of other impurities are formed. These vapors are passed into a milk of lime solution containing about 20 per cent CaO, by which process acetic acid is removed from these vapors and a weak solution of calcium acetate with some tarry impurities is obtained.

The unabsorbed vapors, consisting mainly of alcohol, water and acetone, may be condensed to give a weak alcoholic solution, or may be passed through a concentrating apparatus, consisting usually of water-cooled bonnets, to give a 35 per cent to 40 per cent solution of wood alcohol. The solution of acetate is heated to remove the last traces of alcohol, the alcoholic vapors so formed being united with the others, and the impure solution is then filter-pressed to remove dirt, excess lime, etc., and finally evaporated, first in comparatively small, open, steam-jacketed pans until a thick paste or moist cake is obtained, then in open, shallow iron pans set in brickwork over the retorts until an acetate of lime of 80 per cent to 82 per cent, containing a small percentage of moisture, is obtained.

The manufacture of brown acetate by direct neutralization of impure, settled, pyroligneous acid, with milk of lime, is unimportant, the amount of this acetate manufactured being equal to only 1 per cent of the amount of gray acetate.

The 35 per cent to 40 per cent impure acetone-containing wood alcohol obtained as described is further concentrated in a column still heated by steam coils to give an impure 80 per cent by volume solution, which is not refined at the distilling plant, but in special refiners. The charcoal, which is left in the retort, is removed and cooled in a different manner according to the character of the oven used. With the small, removable retort the whole apparatus is lifted out of its setting and the charcoal either left to cool in the retort itself or dumped into a cooling receptacle. With the small, horizontal fixed retorts the charcoal must be removed by hand from these retorts and placed in a closed receiver to cool. From the large horizontal retorts, however, the charcoal may be removed on the cars into cooling receptacles of suitable size, and when cool may be dumped from these cars where required.

The tar, whether settled out of the pyroligneous acid or removed from it by distillation is in the majority of plants burned under the retorts by suitable arrangements.

This outlines the procedure required for the production of the principal products—gray acetate of lime of 80 per cent to 82 per cent; crude wood alcohol of 80 per cent; charcoal, tar and oils.

These products are then sold to various consumers, either to chemical manufacturers and refiners, iron men and fuel consumers, or for export. Of these products the acetate of lime is used for the production of acetone, acetic acid and various acetates; the crude wood alcohol for the production of formic acid; the refined wood alcohol, pure methyl alcohol or denaturing spirits, and the tar and oils for various purposes.

The amounts of the various products yielded in the distillation process per cord of wood depends, as was mentioned before, upon the kind of wood and the process. This can be shown very well by comparing the average yields returned by the plants of Pennsylvania, where the "retort" process is used, and the object of the distillation is the recovery of all of the product; with those returned by the plants of Michigan, where the "kiln" process is used, and the object is the production of charcoal for use in making charcoal iron. The following figures show this:

State	Process used.	Products per cord.
Pennsylvania	Retort	200 lb. gray acetate of lime.
		10 gal. crude alcohol (80 per cent)
		50 bu. charcoal.
Michigan	Kiln	50 lb. gray acetate of lime.
		4 gal. crude alcohol (80 per cent).
		40 bu. charcoal.

Financial Situation.—The previous outline has given the main details of the process used in distilling wood in America to-day, and in order to understand the present situation of this industry as an investment, the following figures are given, these figures showing the average cost per cord of wood for the years 1906, 1907 and 1908; also the value of the principal products produced during that time.

	1906	1907	1908
Wood per cord (sawdust included)	$3.24	$3.14	$3.09
Wood per cord (sawdust not included)	3.69	3.62	3.57
Charcoal, per bushel	.065	.076	.071
Crude alcohol, per gallon	.340	.149	.172
Gray acetate, per pound	.021	.019	.015
Brown acetate, per pound	.012	.012	.008
Iron acetate, per gallon	....	....	.095
Oils, per gallon	.080	.024	.066

From this table it can be seen that while the price of wood has decreased a very little, the value of the products produced has decreased a very great deal, notably in the case of the crude wood alcohol.

Now this decrease in the value of the products of the wood-distilling industry is due to two factors:

(1) The financial depression of 1907.

(2) The passing of the denatured alcohol acts of 1906 and 1907.

The price of refined wood alcohol was in 1906 about 75 cents per gallon, while that of grain alcohol was about $2.40 per gallon. There are many chemical processes, such as, for instance, the hat and varnish industries, where either refined wood alcohol or grain alcohol can be used, and the cheaper is, of course, preferred. When the denatured alcohol act was passed the price of grain alcohol denatured for industrial purposes was considerably below 75 cents per gallon, and, of course, replaced wood alcohol where possible. The demand for this wood alcohol having diminished, its price naturally fell and carried with it the price of crude wood alcohol, acetate of lime and other wood products, and drove a number of wood distillers out of the business, at the same time seriously threatening the whole industry in this country. At the present time, however, it has recovered somewhat, and the outlook is bright for the future, as will be shown later.

One, and the principal denaturant, prescribed for grain alcohol is wood alcohol, containing certain impurities, and a large amount of such wood alcohol is consumed in this country. The use of denatured alcohol has not become, however, so general here as was expected, but it is probable that there will be a large increase in consumption in the future and that the consumption of wood alcohol for denaturing will be such as to use up all of the supply available for this purpose, thus restoring the prices to their former level. This situation is exactly like that in Germany 20 years ago, when the denatured alcohol act proved a boon rather than a deathblow to wood distillers and refiners.

This was for the reason that there are many purposes, for instance, in the aniline industries, for which very highly refined wood or methyl alcohol only is suitable, in which industries, therefore, the passing of the denaturing alcohol act had no effect upon the demand for wood alcohol. The use of denaturing spirit which required, as mentioned above, a very impure wood alcohol, containing various impurities, such as acetone, allyl alcohol, pyridine bases, etc., thus permitted the pro-

duction of a very pure spirit by distillation and permitted the utilization of the impure first and last runnings as denaturing spirit.

It can be seen that this was a very economical process, since such pure, refined methyl alcohol commanded a very high price, and the demand for denaturing spirit was such as to cause this to sell at a considerable profit. While industries which demand this pure alcohol have not been developed to a great extent in this country, yet there is every prospect of great development along these lines and this fact, together with the prospect of increased consumption of denatured alcohol and the probability that the amount of raw spirit produced here will not be increased, at least for a good many years, makes the outlook for wood-alcohol producers and refiners very encouraging.

While, therefore, it is thought for this and other reasons, particularly the situation of the acetic-acid industry, that the depression in the wood-distilling industry is but momentary, yet recovery will take several years, and in the meantime it will be necessary for the wood distillers to make their processes profitable. This can be done in various ways, which will be outlined. It is a fact well known that the wood-distilling industry has been conducted, at least in this country, by men unacquainted for the most part with the fundamental principles of chemistry and engineering, who have been unable or reluctant to introduce any considerable improvements into their processes, and as a result have been using up to-day the methods of 30 years ago. With the increased costs of fuel, labor and raw materials it is evident that improvements are necessary to maintain the industry in its proper position, but in the wood-distilling industry it is notably the case that improvements which advances in the chemical industry should have made possible have not been introduced.

Improvements.—The rest of the article will be taken up with an outline of the opportunities open to distillers to so improve their plants or processes as to increase their returns in accordance with the following conditions, or to extend their business to more profitable fields. The conditions which are necessary are that they must either

(1) Increase their yield of products or the quality of the same;

(2) Reduce the costs of production either as regards fuel, labor or apparatus.

Each of these conditions will now be discussed separately.

(1) *Increasing the Yield.*—The yield depends on:

(a) The kind of wood.

(b) Condition of the wood.

(c) The form of retort and setting.

(d) The method of heating.

(e) The methods of recovering and treating the products.

As regards the kinds of wood, this method cannot change, but a proper selection will have much to do with the yield obtained. The condition of the wood, however, is very important. The moisture in the wood not only requires heat for evaporation, but, when the temperature of carbonization is reached, causes side-reactions, which result in the formation of gas instead of liquid vapors, thus decreasing the yield of pyroligneous acid to a considerable extent. In this connection only wood which has been air-dried for a year at least should be used, but a further improvement, recently introduced, consists in artificially drying and forewarming the wood before carbonizing, but after packing on the cars, if the large retort is used, by placing these cars in ovens through which the warm or hot-fire gases are passed, for 24 hours before introduction into the retort. This is done practically free of cost.

The form of retort and the setting is very important. In the first place, only large retorts which can be filled and emptied mechanically should be used. This results in a great saving of time and labor. Again, these retorts should be so placed in the setting that they can be heated uniformly over the whole length, and the heating should be so controlled that the temperature is maintained at a constant point and the heat applied slowly. It has been proven by many experiments that rapid heating results in the formation of larger amounts of gas and smaller amounts of pyroligneous acid, while slower heating decreases the yield of gas and increases the yield of acid.

The methods of recovering the products influence the yield to a considerable extent, and in this connection there should be mentioned the use of an exhauster to create a slight vacuum in the retort, thus preventing leaks, and the use of a scrubber whereby the uncondensed gases are caused to pass through a tower and are deprived of any pyroligneous acid vapor which they may contain. This may seem a small matter, but it has been found that by the use of such apparatus the yields of acetic acid and alcohol can be increased 3 per cent to 4 per cent.

(2) *Decreasing the Costs of Operation.*—To decrease these costs there may be used any appliances which tend to:

(a) Decrease the amount of labor required.

(b) Decrease the amount of fuel required.

(c) Decrease the cost of apparatus and depreciation on the same.

We have already considered these items in connection with the carbonizing itself, recommending large retorts, mechanical loading and unloading, together with the use of artificially dried wood as savers of labor and fuel in this part of the operation. Regarding methods of decreasing the costs of labor, fuel and depreciation in the remainder of the wood-distilling operations it might be well to describe the appliances and methods which can replace those now in use, and to then take up the effect of using this apparatus on the above-mentioned costs.

Practically all of the evaporation required in the operation subsequent to the carbonization is accomplished by the use of high-pressure steam, and of this steam required approximately 40 per cent is needed to re-distill the pyroligneous acid to remove the 8 per cent of tar contained in it. Now if this tar could be separated from the pyroligneous acid vapors as they came from the retort without condensation, and the tar-free vapors then passed into the milk of lime, this 40 per cent of fuel would be saved. Such an apparatus has been devised and has been in operation in many plants abroad and a very few in this country for over two years. It has actually been found to almost completely separate the tar from the vapors.

This apparatus, which operates on practically the same principle as a fractional distilling column, yields liquid tar free from acid and a tar-free pyroligneous acid vapor, and is so constructed that it requires no troublesome hand cleaning. The apparatus is not known to any extent in this country, but is destined to occupy a big field. Because of the economy of steam, it permits the formation of a very pure acetate of lime, does away with the condenser and tar still, with all the trouble of cleaning the same. This apparatus occupies little space, is simple in construction, and yields a tar which can be used for producing creosote and other tar derivatives without further treatment.

Another very important appliance, but very recently introduced, is an apparatus by means of which the acetate of lime solution containing traces of alcohol is de-alcoholized, and at the same time the weak alcohol vapors concentrated to give a product, directly, of 90 per cent to 95 per cent, and requiring only the use of the heat of the alcohol vapors and sometimes exhaust steam to accomplish the evaporation. This apparatus works on the principle of the continuous distilling apparatus used in the grain-alcohol distilleries of to-day to a large extent, the wood alcohol produced being analogous to the high-proof spirit delivered from these continuous distillation columns and the de-alcoholized acetate of lime solution to the "slop" from the same.

Special modifications are required in this apparatus, however, to meet the new conditions, but it has been found to work very satisfactorily indeed. In operating this apparatus, the acetate of lime solution is introduced into the first distilling column

after passing through a "heater," while the weak alcohol vapors are passed into the bottom of the same column, thus furnishing the necessary heat for the distillation. The vapors of wood alcohol and water, passing from the top of this column, then go to a second rectifying column and are concentrated to the required proof.

By means of this apparatus and the tar separator, it is possible to do away with the customary "three-still system," also with the wood alcohol concentrating and rectifying apparatus, and by use of the latent heat of vaporization of the weak alcohol vapors for the de-alcoholization of the acetate of lime solution, a saving of fuel amounting to 20 per cent is effected. Besides the saving in fuel, there is a saving in space and labor required, as well as a decreased cost for the first installation.

In the evaporation of the acetate of lime solution great improvements have also been made. The customary method of carrying out this evaporation, as previously described, in open pans, required high-pressure steam, much hand labor for transferring the material and cleaning the pans from incrusting materials, and gave a poor product if not carefully carried out. To do away with this, an apparatus, essentially a form of triple effect with special devices to meet the requirements, has been introduced, and in consequence of the use of a vacuum, the use of exhaust steam is possible.

This apparatus, working continuously, takes the weak of acetate of lime and delivers it in the form of a thick mush. In consequence of the fact that this apparatus permits the use of exhaust steam from the engines instead of the high-pressure steam required by the former method, there is effected a saving of approximately 100 per cent in the amount of fuel required for this operation, while the labor cost is greatly diminished and a better product is obtained. It is needless to say that this apparatus requires less room than that required by the open-pan method, and it is also a fact that the initial cost and depreciation are less in consequence of the fact that no cleaning and scraping are required on the same.

Further than this, improvements have been made in the method of drying this acetate of lime. Where it was formerly dried in the open pans over the retorts, rotary dryers, especially designed for the purpose, can now be obtained. By the use of a dryer heated by superheated steam the mushy acetate of lime is dried to give a moist cake containing 25 to 30 per cent water, which cake is then thoroughly dried in a second apparatus, also rotary, through which hot air, heated in turn by the hot retort gases, passes, and the dry acetate of 80 to 84 per cent, nearly white in color, is delivered by an elevator to a chute from which the sacks can be filled. The essential saving effected by this last apparatus is in labor and space. The labor required is never over 30 per cent of that required by the open-pan method, while the space occupied by the dryers is very much less.

Summarizing the results which may be obtained by the installation of this improved apparatus, it may be said that that amount of coal required for steam production in the plant will be reduced to 35 or 40 per cent of that required by the present customary process, the labor to one-half, and the initial plant cost for a fifty cord per day plant to two thirds that of plant operating under the present methods, while the cleanliness of the plant and space required for the apparatus is also affected. In every case the improved apparatus operates on principles identical with those employed for different products in other industries, with suitable modifications to meet the conditions.

It is evident that the old method now used to a great extent cannot compete for a minute with this improved process. As regards the yields, these are also increased by approximately 10 and 15 per cent. While these improvements have scarcely been introduced into this country, they have been thoroughly tested out abroad, and several plants, notably one large plant in Michigan, distilling over 200 cords per day, are to be remodeled to employ these processes during the coming year. It is to be hoped that persons engaged in wood-distilling industry in this country will not hesitate to adopt these methods and put themselves in position to compete with those who are awake to their opportunities.

* * * * *

The foregoing has related to the manufacture of the crude products of the wood-distilling industry, but the field in which extensive profits are now being reaped and where more extensive profits will be reaped in the future is in the manufacture of the finished products from these raw materials, that is, more particularly, acetic acid, refined wood alcohol, methyl alcohol, acetone, tar derivatives, and various other products, such as red and black liquors, sugar of lead, sodium acetate, etc.

Acetic Acid.—This acid, manufactured commercially from acetate of lime and a strong acid by various processes, is used in the coal tar color industry, in the dyeing and mordanting industries, in the manufacture of artificial vinegar, etc. The manufacture of this acid under improved and economical processes, yielding acid which gives the highest returns, has been in the hands of five large chemical factories up to this time, and it has been a well-known fact that the business is very profitable.

At the present time wood-distilling people producing sufficient acetate to keep an acetic acid plant of economical size in operation in localities adjacent to the large cities, for instance in Pennsylvania, are offered unexcelled opportunities in this industry. There are a number of small firms who have started plants making acetic acid, but without exception they have installed the process using small fire-heated decomposing retorts, and inefficient methods, which require the use of a large excess of raw materials and produce an inferior product, besides increasing the amount of labor required, etc.

An American firm, E. B. Badger & Sons Co., of Boston, has undertaken the installation of acetic acid plants, employing the most improved and efficient methods, notably the use of very large decomposing retorts and a vacuum system such that the fuel cost is decreased, better regulation made possible, a very much better product produced, and increased yields obtained, these improvements being sufficient to make the difference between small and large profits.

Wood distillers who follow the example of two or three plants in Pennsylvania now installing such apparatus will be well repaid. The above-mentioned firm is also in a position to supply the necessary apparatus for the following industries, in all of which they furnish the most improved type:

Refined Alcohol.—The refining of wood alcohol and the production of pure methyl alcohol is an industry where there is great opportunity for improvement in the methods and apparatus used in the majority of plants, also where wood distillers have a good chance for investment.

The refining of crude wood alcohol in this country has been controlled by a syndicate, and what they did not refine has been shipped abroad. The following table of exports shows that a large amount has been exported, also shows the drop in value of this alcohol within the last two years.

Year.	Quantity Exported.	Value.	Value Per Gal.
1902	627,000 gals.	$338,000	$0.54
1903	834,000 "	453,000	.54
1904	1,194,000 "	585,000	.49
1905	1,097,000 "	603,000	.55
1906	781,000 "	466,000	.60
1907	2,150,000 "	862,000	.40
1908	1,958,000 "	819,000	.42

As may be observed, the higher the price, the less alcohol exported, and vice versa.

With the present low price of crude alcohol and the demand in this country for refined wood alcohol and pure methyl alcohol, and probably soon denaturing spirit, it is absurd for distillers of sufficient size to support a refinery to sell their

crude product. They should install a refinery of their own independent of the trust, as several plants have done to their great advantage. In this industry, however, as in all others, it is necessary in order to conduct it profitably to use improved methods and apparatus. In the manufacture of refined wood alcohol, that grade known as English wood spirit is a spirit obtained by concentrating the crude wood alcohol to such a point that it contains only a small amount of water, not over 5 per cent, but still contains many of the impurities of the crude alcohol.

In the manufacture of this grade large continuous apparatus may be very profitably employed, but it is very seldom that a new plant installs such an apparatus, it being a common occurrence to see plants using small apparatus and running their products through two or three times to get the necessary concentration, thus increasing the fuel, labor, and depreciation costs. The continuous apparatus will take the crude wood spirits and turn out the spirit of concentration desired, all in one operation.

In the production of pure methyl alcohol, it is seldom profitable to employ continuous apparatus, since the distillate must be collected carefully between certain limits determined by boiling point, odor and miscibility with water, and must be treated with various chemical re-agents in order to remove the contaminating products. However, the use of large apparatus effects a considerable saving here. Under present conditions the manufacture of this high-grade methyl alcohol, for which there is considerable demand at high prices, offers very good opportunities, since the impure spirit obtained in the process, which amounts to 60 to 70 per cent of the crude spirit used, is available for denaturing at good prices.

Acetone.—The manufacture of acetone, extensively used as a solvent, especially in the smokeless powder and celluloid industries, is another of these refined products which may be manufactured. Acetone is manufactured from acetate of lime by dry distillation, and is extensively manufactured in this country, although the methods used in many plants are, as in the other industries, inefficient and uneconomical. Process, however, have been devised whereby a product of greater purity may be as readily produced, and offers great opportunities in this industry.

The utilization of the wood tar is a subject that is but little considered, and the majority of plants burn their tar under the retorts. This tar, however, usually contains enough creosote to make it profitable to work. This creosote is a product of indefinite composition, which is much used for producing rosolate of soda, from which sulphuric acid precipitates rosolic acid, a color much used in yellow dyeing or calico printing, and it is also an excellent germicide and disinfectant. It has been profitably extracted from wood tar and wood distilleries in Canada, where it paid to burn coal in the place of tar, and it is evident that in the United States, especially in Pennsylvania, where coal is so cheap, there should be still greater opportunities for working this material and burning coal instead. Plants for refining this tar so as to obtain this creosote, consisting of stills and columns of appropriate design, can be furnished in this country.

From this brief and incomplete outline of the industry in the United States and its possibilities, it is evident that the opportunities open to wood distillers are not as poor as they may have appeared for the last two years, but that rather a large field for profitable investment is open to progressive manufacturers.

Chemistry Exhibits of the American Exposition in Berlin, 1910.

The committee in charge of the American Exposition, to be held in Berlin from July to October, has taken note of the vast importance the chemical and allied industries bear to the trade relations between Germany, commercial Europe, and the United States, and has set aside for the use of these industries some thousand square feet of space for their exhibits.

Mr. E. H. Johnson, a prominent printing-ink manufacturer of Philadelphia; Mr. R. H. Lersner, of the firm of C. M. Childs & Company, New York; Mr. I. F. Stone, president of the Chemists' Club, of New York, and Mr. Eugene A. Widmann, secretary of the H. A. Metz Company, New York, have been asked to serve as a committee on the chemical exhibits and have accepted this invitation. Mr. Widmann, chairman of this committee, can be reached at 30 Church Street, New York City.

There is no need of drawing attention to the immense exchange of chemical and allied products between the United States, Germany, and European as well as Asiatic countries. Berlin, being the commercial center of Continental Europe, offers a very fertile field not only for the manufacturer of the general line of chemicals, but for the maker of specialties. Buyers from Russia, Norway, Sweden, Italy, Turkey and other countries, and even Asiatic countries, as China and Persia, gather in this city to obtain the larger percentage of their wants.

To the American chemical industry a chance is thus given to find new markets by exhibiting the products of their factories at the coming Berlin exposition. By making their wares known in Berlin, their name and brand reach those numerous other countries.

The exposition has the endorsement of both the American and German Governments. Mr. J. Pierpont Morgan is honorary president; Mr. David R. Francis, who was president of the Louisiana Purchase Exposition held at St. Louis, is first honorary vice-president; Mr. John Wanamaker is second vice-president; Dr. George F. Kunz is president of the advisory committee, and Mr. Herman A. Metz is chairman of the executive committee. In Germany, Prince Henry of Prussia is to act as president of the reception committee.

While going to press we are informed that the exhibition will probably be postponed to the year 1911.

A Double-Zone Gas Producer for Bituminous Coal.

At a meeting of the Mechanical Section of the Engineers' Society of Western Pennsylvania, held in Pittsburgh on Dec. 7, 1909, Mr. E. F. Bulmahn, engineer of the gas-producer department of the Westinghouse Machine Company, read a paper on their bituminous power gas producer.

There are two classes of gas producers: pressure producers and suction producers. The question of the relative economy of these two classes of producers is more a matter of design than of theory. However, considering the economy of the two as equal, the sanitary conditions attending the operation of the suction producer is enough argument in its favor.

The two foregoing classes of producers are again divided into three distinct types, viz.: updraft, downdraft and double-zone producers.

The advantages of the updraft producer (fuel charged at top, air introduced at bottom, gas taken off at top above the fuel bed) are the production of a gas of high heat value and complete consumption of the fixed carbon in the fuel. Its disadvantage is that a large percentage of the volatile matter in the fuel is carried off in the gas as tar.

This disadvantage is overcome in the downdraft producer (air introduced at the top of fuel bed and gas taken off at the bottom). By passing the volatile matter, given off during the coking of the coal, through incandescent carbon the tarry vapors are fixed into permanent gases, CH_4, H_2, and CO, producing a fixed gas free from tar. In this type of producer, however, it is impossible to completely consume the fixed carbon. The breaking up of the tarry vapors and the reduction of CO_2 to CO requires from 3 ft. to 4 ft. of incandescent fuel. The oxygen introduced on top of the fuel bed after it has traveled about 2 ft. below the top has combined with carbon to form CO_2 so

that the only carbon recovered in the fixing zone is that taken up by the CO_2 gases in reducting to CO. This results in a high carbon loss in the ash.

The **double-zone** producer is designed to embody the good features of both the updraft and downdraft producers, overcoming the production of tar and completely consuming the fixed carbon. This is accomplished by having two distinct fuel beds, one operated as a downdraft producer, to break up the volatile matter, and the other operated as an updraft producer to consume the fixed carbon, the resultant gas from each zone being taken off at the center of the producer.

The double-zone producer built by the Westinghouse Machine Company was the special subject of Mr. Bulmahn's paper. It is illustrated in Fig. 1. It consists of a top and bottom shell, interposed between which is a circular iron vaporizer, which

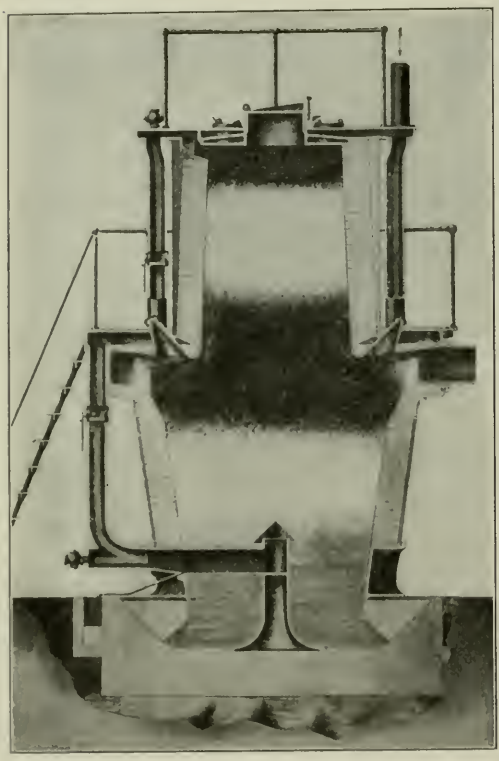

FIG. 1.—BITUMINOUS GAS PRODUCER.

furnishes steam for the producer and also serves to form the gas offtake. Air for combustion is drawn through the vaporizer, being saturated with water vapor, and is led through two pipes to the top and bottom fuel beds, the amount going to each one being regulated by two graduated cocks placed in the pipe line.

The producer is of the water-bottom design, permitting the removal of ash during continuous operation. The top of the producer is provided with a large coal-charging door, which when opened allows the operator to examine the entire top of the fuel bed. Poking is provided for by a series of poke holes through the vaporizer to take care of the bottom fuel bed, the top being poked through holes located on top and through the charging hole.

In the operation of the producer, it is filled completely with incandescent carbon. Coal is charged on top of the fuel bed and air admitted for its partial combustion. The volatile matter given off passes downward through the incandescent carbon, where it is broken up into fixed gases. The coke formed passes down through the producer, being consumed in its travel through the bottom shell, until finally reduced to ash. The gas formed in the bottom fuel bed passes upward, being taken off at the vaporizer with the gas from the top fuel bed.

From the producer the gas passes through a vertical baffled pipe, provided with a water supply for the removal of heavy impurities, to the washer (Fig. 2). The lower end of the pipe is dipped into a water seal and carries away the waste water.

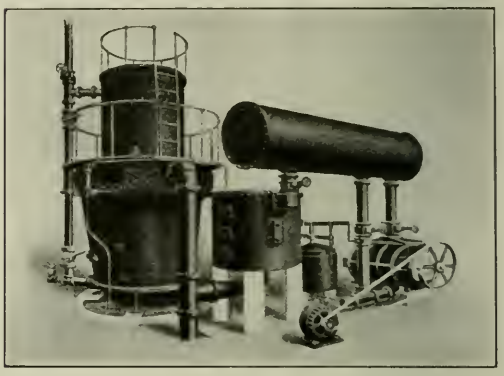

FIG. 2.—GAS PRODUCER PLANT.

The washer is a cast-iron shell, containing a series of three perforated diaphragms, immersed in water. The gas passing through the small perforations deposits its solid impurities, consisting of light ash and lampblack, and is cooled by the incoming water supply. This type of gas washer and the absence of scrubbing material makes possible the continuous cleaning of the gas and displaces the mechanically driven high-speed cleaning apparatus usually employed.

From the washer the gas passes into a cylindrical shell which is used as a mixing tank. The exhauster draws the gas from the mixing tank, maintaining a suction on the producer, and delivers the gas under pressure. When a fuel containing volatile matter is charged on an incandescent fuel bed, the gas given off during the first five minutes is highly enriched, due to the hydrocarbons given off from the volatile matter. The usual method of overcoming this variation in the gas is to provide sufficient holder capacity to equalize the quality. In the Westinghouse producer the exhauster delivers an excess quantity of gas, the excess passing into the mixing tank, where it is mixed with the lower-heat-value gas. The amount is controlled by a gasometer regulator and valve, which also serves to maintain a constant pressure in the gas outlet pipe. This gives a continuous circulation of gas through the mixer and insures an even quality of gas.

The adjoining table gives the results of a 51 weeks' continuous test of a 175-hp double-zone producer and a 15 by 14.3-cylinder gas engine. The plant was operated both 24 and 10 hours a day, the tests covering periods of from 10 to 30 days. Seven different fuels were tested as shown in the table, which gives the composition of the fuels and the economy of operation of producer and gas engine when operated with these fuels.

These tests demonstrate the adaptability of this type of producer to handle fuels, covering a wide range of heat values, and particularly the low-grade fuels. The capacity of the producer was not materially affected by any of the different fuels, except peat, with which fuel the capacity was considerably reduced.

The gas made from all the fuels was reasonably free from impurities, the solid matter averaging not more than .025 grains per cu. ft. of gas. As all the tests were made with the same engine, it afforded an excellent opportunity to note the effect of the gas on the engine. After a run of over 1000 hours, the inlet and mixing valves were removed from the engine for inspection. A slight coating of lampblack was found, but from all appearances it should have operated even a longer period without requiring cleaning.

in the manufacture of steel and glass, the producers being of the updraft type and the gas is used hot and uncleaned. There are a great many applications, however, where the gas must be distributed through small pipes, throughout a plant, and consumed in small burners, and a cool, clean gas is required. This gas may be applied to small tempering furnaces, annealing ovens, enameling kilns, hardening, blueing and baking ovens, small melting furnaces, etc. It makes a particularly inviting proposition where power is required and a portion of the gas

* Net efficiency.
† Producer operated 10 hours a day. Fuel consumption and combined efficiency includes stand-by coal 14 hours per day.

The gas made on all the tests was of a good quality and reasonably constant in heat value. The average thermal value on bituminous coals was about 115 B.T.U., being a little higher on lignite gas. The heat value of the gas is rather low, compared with gas from an updraft producer. The reduction, however, is due to the lower H_2 and CH_4, content, a lower H_2 content being desirable for gas engine operation allowing higher compression and advanced ignition setting.

The labor required to operate the producer is comparatively small, it requiring about twenty minutes per hour of one man's time to perform all the labor on a 175-hp unit, using a Pittsburgh coking coal.

The standby loss of the producer when operating 55 hours may be used as fuel, as the labor on the producer in most cases would be the same.

Mr. Bulmahn gave in his paper diagrams showing the results of tests of a producer-gas-fired crucible furnace for melting copper billets. In one of these tests the gas and air were preheated, by utilizing the heat from the waste gases from the furnace. In the other test the gas and air were used at practically atmospheric temperature. A comparison of both tests shows the effect of preheating, in an appreciable increased economy in gas consumption, in higher furnace temperatures attained, and in the decreased amount of time required to take off a heat.

The paper elicited a very extended discussion, which is

per week represents about 0.9 per cent of the fuel when used when operating at full load.

Fig. 3 shows the producer efficiency curve, plotted from the above mentioned tests. It is particularly interesting in that it conforms to so wide a range of fuels and on account of the slight differences in the producer efficiency between one-half and full load.

The industrial applications of producer gas offer a wide field for gas producers. They are now quite extensively used

printed in full in the *Proceedings* of the Engineers' Society of Western Pennsylvania for January. In reply to several questions, Mr. Bulmahn explained that in the operation of the producer the idea is that in the top half of the producer all that is expected to be done is to coke the fuel and drive off the volatiles, the bottom working on carbon and ash only, so that the bottom fuel bed is operated as a simple updraft producer.

Finally, Mr. Bulmahn stated that with a double-zone pro-

ducer there is less trouble from clinker than in a single-flow producer, for the reason that having two combustion zones, with practically the same area, it gives a slower rate of combustion and a slower velocity through the fuel bed. This results in lower temperatures, preventing the formation of clinkers. Some clinkers are formed when starting the producer with a cold vaporizer. These usually form about the tuyere and are easily removed from the poke holes, of which there are about eight around the circumference of the vaporizer. On intermittent operation it usually takes about 15 minutes after starting the producer before the average amount of steam is generated.

In comparing an anthracite suction producer with this double-zone bituminous producer, Mr. Bulmahn said that in the latter there are some impurities in the form of lampblack and probably the carbon content in the ash is a little higher than with an anthracite producer, which causes a slight additional loss in the efficiency of the producer. The average efficiency of an anthracite suction producer tested by him was about 80 per cent, as against 77 per cent for the bituminous. As to the practicability of the two, while the bituminous producer requires a little more labor than the anthracite, he thinks that it is to-day more reliable than the anthracite for this reason. With a fuel containing volatile matter and where one does not depend entirely on the working reaction, that is the combination of carbon and oxygen, a little irregularity in the fuel bed will not be felt as much in the bituminous as in the anthracite producer.

As a basis of comparison between natural gas, fuel oil, and fuel gas (producer when) applied to smelting or heating furnaces, the following figures were given by Mr. J. K. Lyons.

Calorific values are assumed as follows:

	British Thermal Units.
Natural gas, per cu. ft	1,000
Fuel oil, per gallon	125,000
Fuel gas, per cu. ft (producer)	145

The following quantities are required for one million British thermal units:

Natural gas	1,000 cu. ft.
Fuel oil	8 gallons
Fuel gas (producer)	6,900 cu. ft.

The following table gives the equivalent costs per thousand cubic feet for natural gas and per gallon for crude oil, when compared with producer gas generated from bituminous coal with recovery of sulphate of ammonia as a by-product.

It is assumed that the plant will gasify not less than 48 tons of coal per 24 hours.

Cost of Coal Per ton.	Equivalent price for natural gas per 1000 cu. ft.	Equivalent price for fuel oil per gallon.
$1.25	2.208 cts.	0.276 cts.
1.50	3.588 "	0.4485 "
2.00	6.348 "	0.7935 "
2.50	9.108 "	1.1385 "
3.00	11.868 "	1.4835 "

The above prices cover the cost of the coal and operating costs, but interest charges and depreciation and the auxiliaries are not included. If the fuel gas is used for operating internal combustion engines, the heat in the exhaust gases from the engines would be utilized in waste heat boilers, which would afford ample prevision for all auxiliaries and without any addition to the operating costs.

An Efficiency Test of a Direct-Heat Dryer.

In connection with the various articles on dryer design and operations which have been published in recent numbers of this journal and which indicate that a high degree of perfection of design has now been reached on sound scientific principles, we are pleased to call attention to a short, but interesting article of Mr. W. B. Ruggles, president of the Ruggles-Coles Engineering Company, of New York, in the February issue of *Cassier's Magazine*.

Mr. Ruggles points out that while the determination of the total efficiency of the dryer using direct heat is a simple matter, it is not so easy to discover where the losses occur. There are four ways in which losses may occur—in unconsumed carbon, due to imperfect combustion; in heat carried out by the exhaust gases; in heat carried away by dried material, and in radiation from the furnace and shell.

Imperfect Combustion.—The loss due to imperfect combustion is generally ignored or rather included in the loss by radiation. However, recent tests have shown it to be a considerable factor, unless a large combustion chamber is supplied, in which space and time are given for the perfect combination of oxygen with the carbon monoxide. When the dryer is so arranged that the flames impinge directly upon a cascade of cold and wet material they are quenched suddenly and a considerable amount of carbon passes off unconsumed. This, in certain types of machines, may amount to 7 per cent or 8 per cent of the value of the fuel.

Heat in Exhaust Gases.—The heat carried away by the exhaust gases is generally the largest item of the losses and sometimes amounts to 30 per cent or more, but, as Mr. Ruggles points out, this is chiefly the case in dryers in which natural draught is used, because in this case the temperature of the stack gases is seldom below 400° Fahr., and often 600° or more. He, therefore, strongly recommends to use an exhaust fan and draw the gases against the flow of drying material, so that just before leaving the dryer it has been in contact with the cold and wet material. Undoubtedly some condensation occurs of the steam being carried out, but there is no ultimate loss, as the heat given up in condensation is absorbed by the material and aids in drying later in the process. When the current of the gases is reversed and flows in the same direction as the material, a temperature of at least 212° Fahr. must be had in the exhaust, so that no condensation may occur and moisture deposited upon the finished material.

Heat in Dried Material.—It is, of course, a matter of definition how much of the heat which is carried off by the dried material should be considered as a loss. In general, a temperature of 212° of the dried material leaving the dryer is necessary to the rapid drying of the material. But, as Mr. Ruggles points out, all heat of the material above 212° is unnecessary in most operations, and, therefore, should be charged as a loss. This is generally not great, and is, in most cases, due to imperfect operation and not to the design of the machine.

Radiation.—The radiation loss depends greatly on the design of the dryer. "In some, the shell is cool enough to place the hand on without discomfort; in others, it is not uncommon to see the shell red hot for 10 ft. or 12 ft. from the furnace. This, of course, is in a single-shell type, in which the flames impinge directly upon the shell. The loss by radiation in such a dryer is very great. In a bricked-in machine the temperature is not so high; but, as more surface is exposed, the total loss is almost as great." In general, the radiation loss is determined by difference of the total loss and of the other losses.

The following figures of a recent dryer test given by Mr Ruggles are very instructive as the test has evidently been carried out with great care. The coal used for fuel was dried and tested calorifically. The flue gases were measured by an aerometer and analyzed for CO, and the material tested for moisture and specific heat. The figures are given in round numbers.

It will be seen that the very high efficiency of 85.8 per cent of the dryer under test was found.

Amount of coal burned per hour	400 lb.
Amount of moisture in coal	10 per cent
Calorific value of dry coal	13,000 B.t.u.
Material Dried—Bank Sand.	
Amount of wet material per hour	45,000 lb.
Amount of dried material per hour	42,750 lb.
Specific heat of sand	.21
Moisture in sand	5 per cent
Temperature of air, sand and coal	60° F.
Temperature of dry sand	224° F.
Total moisture in coal	40 lb.
Total heat per pound of water 60° to steam	1,122 B.t.u.
Heat required to evaporate water in coal $40 \times 1122 =$	44,880 B.t.u.
Total heat in dry coal $360 \times 13000 =$	4,680,000 B.t.u.
Total heat for drying $4680000 - 44880 =$	4,635,120 B.t.u.
Specific heat required to heat sand 60° to 212°, $42750 \times .21 \times 152 =$	1,364,580 B.t.u.
Total water in sand	2,250 lb.
Total heat required to raise temperature of moisture and evaporate same $2250 \times 1122 =$	2,524,500 B.t.u.
Theoretical heat required	3,889,080 B.t.u.
Efficiency of dryer $\frac{3889080}{4635120} =$	85.8 per cent
Total losses in dryer	14.2 per cent
Excess temperature of sand	12°
Loss by same $42750 \times .21 \times 12 =$	117,730 B.t.u.
Percentage $\frac{117730}{4635120} =$	2.5 per cent
Quantity of air exhausted @ 100° per hour	450,000 cu. ft.
Weight of air exhausted @ 100° per hour	31,905 lb.
Loss by excess temperature $100° - 60° =$	40°
Specific heat of air	0.2374
Loss in exhaust air $31905 \times 40 \times .2374 =$	302,960 B.t.u.
Percentage $\frac{302960}{4635120} =$	6.5 per cent
Amount of CO in exhaust gases per hour	3.4 lb.
Value of CO as fuel, per pound	10,100 B.t.u.
Total loss $10100 \times 3.4 =$	34,340 B.t.u.
Percentage $\frac{34340}{4635120} =$	.7 per cent
Recapitulation.	
Loss by excess temperature of sand	2.5 per cent
Loss by heat of exhaust gases	6.5 per cent
Loss by imperfect combustion	.7 per cent
Loss by radiation and other causes	4.5 per cent
Dryer efficiency	85.8 per cent
	100.0 per cent

This test thus shows the surprisingly high efficiency of 85.8 per cent, which is explained by the fact that the dryer under test had almost perfect combustion, very low exhaust temperature, and that the average temperature of furnace and shell was not over 150° Fahr.

Moler Bricks

So much interest has been attracted by the article on moler bricks, published in our November issue, 1909, that we add here some further details for which we are obliged to the manufacturers, Frederiksholms Tegl- & Kalkvaerker, Copenhagen, Denmark. They are making the bricks for partitions, ceilings, etc., in sizes up to 240 mm by 240 mm by 150 mm size (9½ in. by 9½ in. by 6 in.). Particulars of the composition of the "molar" earth are given in the following chemical analysis, viz.:

Silica	67.8 per cent
Alumina	6.7 " "
Iron oxide	5.5 " "
Lime	1.2 " "
Magnesia	0.9 " "
Carbonic acid	Trace
Sulphuric acid	0.6 per cent
Loss by heating	7.4 " "
Hygroscopic water	8.3 " "
Alkalies (by difference)	1.6 " "
	100.0 per cent

The weight of a moler brick of Danish normal size, 230 mm x 110 mm x 55 mm, is about 1.30 kg, while an ordinary brick weighs about 2.50 kg.

The specific gravity of a moler brick is about unity. Pressure tests of a moler brick made on June 11, 1909, showed an average strength of 156 kg per square centimeter.

Moler brick can be supplied in all European sizes, both solid and perforated. Special moler bricks are made for ceilings, arches, partitions, etc. On account of their extreme lightness, combined with unusual strength, the moler brick is recommended for partitions, ceilings, arches, etc., and, further, owing to their insulating properties, it is specially suitable for bricking steam boilers (but not to take the place of firebrick), for inner walls of hot rooms and for cooling stores, etc. They cannot be used as outside bricks on account of their porosity. Moler bricks possess special deafening qualities and are greatly to be preferred to plaster for partitions.

The following special tests of moler bricks were made by the Royal Danish Bureau for Testing Materials:

In a fire test made at one of the Copenhagen municipal gas works, it was proved that moler bricks could withstand a temperature of 1100° C. without the stability of the wall being affected.

An insulation test was made in the following manner: Three testing chambers were built close to each other above the furnaces. One of moler bricks with lime mortar, one of common bricks with lime mortar, and one of Glenboig firebrick in fireproof mortar, silica brick (fireproof) in fireproof mortar, and Kulmit brick (fireproof) in fireproof mortar. Each of the testing chambers was 18 in. square.

The test was continued for three weeks. The temperature at the surface of the furnace was 164° C. to 170° C.; in the upmost layer of moler bricks it was 63° C.; in the upmost layers of the other insulating refractories it ranged from 73° C. to 74° C., showing a difference in favor of moler bricks during the whole period of the test of at least 10° C.

Precious Metals in Colorado.

The precious metal production in Colorado for the year of 1909 was valued at $42,575,878. It is distributed as follows:

Metal and amount.	Value.
Gold, 1,303,713 oz. at $20.67	$29,949,803
Silver, 11,614,500 oz. at 51.5 cents	5,981,461
Lead, 34,023 tons at $85.60	2,912,289
Copper, 12,829,561 lb. at 13 cents	1,667,843
Spelter, 24,262 tons at $107.20	2,600,920
Chemicals from Colorado ores	1,701,562
Tungsten, 1100 tons at $360	396,000
Vanadium, 120,000 lb. at $2.50	300,000
Uranium, Gilpin County	35,000
Manganiferous iron-silver ores	15,000
Pyritic iron-silver ores	16,000
Total	$42,575,878

The total increase over the 1908 products is $9,292,867, distributed as follows: Gold, $4,254,227; silver, $1,006,033; lead, $426,618; spelter, $806,317, and copper, $284,110.

The Vinson Walsh research fund has stimulated the search for pitchblende ores throughout the State of Colorado. The output of radioactive ores has doubled. Ores of vanadium and uranium, including carnotite, are found in the Gilpin, San Miguel and Ouray districts. The hunt is being directed by the Colorado School of Mines at Golden.

Boulder County leads the United States in the production of tungsten with a total of $396,000 against a total of $135,000 in 1908. The 1907 production was $550,000. The 1908 market was against production. Since the first of last July, however, an improvement in quotations started output at a rate that may make the 1910 product $1,000,000 in view of the $7 per unit price. The average price last year was $6 a unit for the 60 per cent fine material, or $360 a ton. The Primos mill of the Primos Mining and Milling Company received $200,000 of the total paid for tungsten. This mill will have a competitor in 1910 buying and shipping concentrates.

Colorado dividends in 1909 show totals as follows: Gold mines and placers, $6,403,853; gold-silver mines, $1,946,500; silver-lead mines, $740,000; gold-lead mines, $75,000; silver mines, $100,000; gold-tungsten mines, $125,000; total, $9,390,353.

The total record of seven smelting companies treating Colo-

rado ores in 1909 was $24,124,953. Some of these treated zinc only, but most of them treated three, and some all five metals —gold, silver, lead, copper and zinc.

The chlorination mills in the State are credited with a production valued at $12,589,874. The only amalgamation mill, the Tom Boy, at Telluride, produced $487,486. The output of the cyanide mills was worth $1,614,072.

The figures given are from the report of the State geologist of Colorado.

Oxy-Acetylene Cutting.

An interesting application of the oxy-oxy-acetylene torch for cutting metal is shown in the adjoining pictures illustrating the use of this process by the American Oxygen Company of Philadelphia for cutting holes thirteen feet in circumference in the steel piling of the new permanent intake well for

FIG. 1.—CUTTING WITH OXY-ACETYLENE TORCH.

the new Chester Water Supply system, for the city of Chester, Pa.

The holes were cut in the bottom of the well after the piling was driven into place, and were for the admission of the water conduits.

The web of the piling is ⅜ in. thick, while the male ends were 2 in. thick by 2 in. wide.

Those familiar with the use of pneumatic tools will readily see that cutting such holes as these by that method would have been a slow, difficult, and expensive operation, particularly as it would have been necessary to cut the male ends with a hack saw. The cutting in this instance was easily accomplished with the standard portable plant of the American Oxygen Company, the operation requiring only minutes, where hours would have been consumed in accomplishing the same results with compressed air tools and saws.

This is only one of the many instances where the oxy-acetylene process has proved itself a valuable factor in construction work. It is stated that the great expense of cutting such passages with air tools and by hand was formerly a very serious argument against installations of this nature. As this difficulty has now been overcome by the oxy-acetylene process, it will be readily seen that the field for steel piling installations will be greatly enlarged.

Swedish Titaniferous Iron Ores.

Concerning the deposits of titaniferous iron ores in Sweden, Consul-General E. D. Winslow, of Stockholm, in a recent report, furnishes the following information: The largest deposit of titaniferous iron ore in the middle of Sweden is Taberg, in the Province of Smaland, seven miles south of the town of Jonkoping. This small mountain is 450 ft. high and consists entirely of this iron ore. The area is figured to be 2,800,000 sq. ft.

The ore is called magnetite olivinite, being at the same time a species of hyperite, holding a comparatively small percentage of iron, which is generally not higher than 32 per cent in the purer sections, and sometimes only reaches 21 per cent. There are besides some smaller veins of rich ore, holding up to 60 per cent of iron, but these veins have only a thickness of about 3 in. The proportion of titanic acid is about 4 to 8 per cent. The presence of phosphorus is 0.055 to 0.10 per cent.

The largest deposits of titaniferous iron ore on the northern parts of Sweden are Ruotivare and Vallatj, situated 10 miles northwest of Kvikkjokk Church, in the Province of Norrbotten. The distance to the nearest harbor on the Norwegian coast is 68 miles over rocky mountains, and the distance to Jokkmokk, in Sweden, is about the same, mostly over navigable lakes and streams. A new addition to the State railway of Sweden, now under construction, will connect Jokkmokk.

The ore at Ruotivare consists of a mixture of titaniferous magnetite, ilmenite, spinelle and olivine. The area has been figured at 3,240,000 sq. ft.

Gold and Silver in 1908.

According to the joint report of the United States Geological Survey and the Bureau of the Mint the production of gold in this country during the calendar year 1908 amounted to 4,574,340 fine ounces, which represents a value of $94,560,000.

FIG. 2.—STEEL PILING.

The figures show an increase of 109,513 fine ounces, or $64,124,300 over the preceding year. The production of silver was 52,440,800 fine ounces and was valued at $28,050,600, this being a shrinkage from the 1907 figures of 4,073,900 fine ounces, or $0,240,900.

In addition the production of home smelters and refineries handling foreign ore, matte, and unrefined bullion, was as follows: Gold, 892,138 fine ounces, or $18,442,100; silver, 65,107,220 fine ounces, or $34,506,800. This supply was de-

rived chiefly from Mexico, Canada, South America, Central America, Korea, and Japan.

In the native production of gold, among the States and Territories, Colorado led with a total value of $22,871,000, while Alaska and California were close behind, credited with over $19,000,000 each.

The year's increase in gold production was thought to be due, in one degree, to the closing of many mines in the base-metal camps. A tendency toward increased production among small operators was noted. Large numbers of miners left the districts in which the output of lead, copper and zinc was curtailed and turned to placer work or took up leases in the gold camps. This depression in the base-metal industries did not otherwise affect the gold production, for the total contribution from the source amounts to but 7 per cent of the normal gold output.

Placer gold made 28 per cent of the whole production, and gold from siliceous ores amounted to 65 per cent. The base-metal ores, in spite of an exceptionally heavy tonnage, gave but 7 per cent. This shows that it is futile to look for a heavily increased production of gold from a stimulated activity in these ores.

Notes.

American Electrochemical Society.—The date of the annual meeting to be held in Pittsburgh has been changed at the request of the local committee. The meeting will not be held in the last week of April, but on May 5, 6, 7. The local committee has already outlined a very attractive program.

New York Section American Electrochemical Society.—A meeting will be held on March 16 in the Chemists Club. Dr. Baekeland will address the section on the Eighth International Congress of Applied Chemistry to be held in this country in 1912. Dr. F. Zimmermann, of Newark, N. J., will present a paper on the Decomposition of Carbon Monoxide at Certain Temperatures in the Presence of Various Catalytic Agents. Dr. R. Stevenson of the College of the City of New York will read a paper on Electrode Reactions.

The South African Institute of Electrical Engineers.—The only society connected with the electrical profession in South Africa—has recently been formed and with the promises of support already extended to it, a membership of over 500 is shortly anticipated. Mr. Fred. Rowland, 9 Transvaal University College Building, Johannesburg, Transvaal, is the secretary.

The Susquehanna Smelting Company has decided to close its electric furnace plant for the manufacture of ferrosilicon in Lockport, N. Y., on account of the continued unsatisfactory condition of the ferrosilicon market and difficulties in regard to obtaining an extension of lease for its present plant, which is owned by the Holly Manufacturing Company, of Buffalo. Ferrosilicon is now manufactured on a large scale in this country by the Electro Metallurgical Company (with works in Kanawha Falls, W. Va., and Niagara Falls, N. Y.). A Canadian company is operating at Welland. Metallic silicon is made by the Carborundum Company.

The Mexican Institute of Mining and Metallurgy.—The regular monthly meeting of this organization was held at the School of Engineers in the City of Mexico. The members of the Institute came by reason of a special invitation from the director of the school, and they made a complete inspection of the principal departments.

Nickel in Canada.—The Mines and Minerals Committee of the Canadian House of Commons has taken up an investigation regarding the nickel resources of the country and the condition of the trade in that metal. It has been thought that the high price at which nickel is held has unduly limited the development of the immense deposits which are available.

Preliminary Mint Report for 1909.—The production of both gold and silver by the mines of the United States increased in the calendar year 1909, according to the preliminary estimates made by A. Platt Andrew, Director of the Mint. These figures show the gold product to have been $99,232,200, against $94,560,000 for 1908; silver, 53,849,000 fine ounces, an increase of 1,408,200 fine ounces. At the average price of silver—$0.52016 a fine ounce for the year—the commercial value of the silver product for 1909 would be $28,010,000.

Large Gold Export.—A recent government report showed that the year 1909 witnessed the outflow of $132,880,000 gold from the United States. This is an unexampled record. In 1904 there was shipped $121,211,000, and in 1895 $104,967,000; no other year on the record approaches 1909. The actual balance of exports over imports last year was $88,793,000; in 1904 it was only $36,408,000, and in 1895 $70,571,000.

Montana Copper in 1909.—In spite of the low prices prevailing for copper the yield of the Montana mines for last year is placed by William Walsh, State mine inspector, at a figure slightly in excess of the preceding year. Mr. Walsh estimates the output of the State for 1909 as follows: Copper, $46,000,000; gold, $4,000,000; silver, $8,500,000; lead, $2,000,000; total, $60,500,000. From every district in the State come reports of renewed activity, and this is especially true of the Butte, Corbin, Helena, Saltese, Jardine, Basin, Zortman, Boulder, Dillon, Clinton and Libby districts.

Mexican Mineral Products.—Following is a résumé of the total values of the nine products for 1909, according to the report of the Minister of Finance to the Mexican Congress: Gold, $45,014,954; silver, $77,109,742; copper, $20,383,000; lead, $6,397,000; zinc, $1,043,000; iron, $1,200,000; other metals, $2,052,158; coal, $4,400,000; mineral oil, $2,800,000; total, $160,399,854.

Petroleum.—The world's production of petroleum in 1908, as given by the *Chemiker Zeitung,* amounted to 38,052,233 tons. In 1907 35,032,235 tons were produced. There was thus a material increase. The production in tons for the two years itemized by countries is given below. The United States is credited with an output about three times as great as that of any other country:

Country.	1908.	1907.
United States	23,942,997	22,149,862
Canada	70,400	105,200
Mexico	464,188	133,855
Peru	134,824	8,732
Russia	8,291,526	8,247,795
Dutch India	1,143,243	1,116,946
Galicia	1,754,022	1,175,974
Roumania	1,147,727	1,129,097
British India	672,938	579,346
Japan	276,124	268,129
Germany	141,900	106,379

India's Mineral Production.—A summary of the mineral production of India for 1908, which appeared in a recent issue of the official *Indian Trade Journal,* states that the total value of the minerals reported in that year was $38,074,254, as against $34,354,400 in 1907. The heavy output of coal contributed the principal share to the increase, but there was also an increase in gold, petroleum, salt, saltpeter, jadestone, graphite and magnesite. On the other hand, there was a reduced output of manganese ore, mica, ruby, tin, iron ore, chromite and diamonds.

European Zinc Combine.—Referring to a report regarding the European zinc trust, Consul H. Albert Johnson, of Liége (Belgium), says that it appears that the various zinc concerns making up the trust are arranged in two principal groups. The first group comprises 18 concerns, principally the zinc works of Upper Silesia and Westphalia, certain Austrian concerns, and several Belgian works. This group is organized as a German company. In Silesia the Heritier George Van Geische Company has remained outside the syndicate, although in many ways closely associated with it. The production of the first group has been limited for 1909 to 255,086 metric tons (280,595 short tons) and for 1910 to 264,232 metric tons (290,655 short tons). The second group comprises the zinc works mainly located in Belgium, notably the Vieille Montagne Company. The production of this group is limited to 174,519 metric tons (191,971 short tons) for 1909 and to 175,919 metric tons (193,511 short tons) for 1910.

Metallurgy in Norway.—By action of the general meeting of the Meraker-Gruben Company, the works of that concern were closed the middle of December, the reason assigned being the poor condition of the ore market. One of the principal owners was the Frankfurter-Metall-Gesellschaft. This company bought the mines 40 years ago and invested 2,500,000 kroner therein. The Erjes Nickelwerk have increased their capitalization to allow an enlargement of the works.

Geological Survey Changes.—Owing to the recent resignation of Professor H. K. Barrows, of the Massachusetts Institute of Technology, as district engineer of the Geological Survey for New England and New York, a rearrangement of district chiefs has been made. Mr. C. C. Covert will be in charge of New York, Mr. Cyrus C. Babb will direct the work in Maine, while Mr. T. N. Norcross will be district engineer for the remaining New England States.

Lin Sheshun has taken formal possession of the standards of weights and measures which the Chinese Government ordered last spring from the International Office of Weights and Measures, in Paris, for the purpose of introducing the metric system in China, in conformity with a law promulgated in 1908.

Aluminium Castings.—The Valley Foundry Company of Canal Dover, Ohio, has recently been organized for the manufacture of aluminium and probably brass castings.

Addition to Foundry.—The Commonwealth Steel Company, at St. Louis, Mo., is completing an addition of its foundry which will increase the capacity about 40 per cent.

Pressure and Vacuum Gauges form the subject of a booklet published by the Schaeffer & Budenberg Manufacturing Company, of New York City. Indicating instruments for measuring pressure, temperature and speed are dealt with in the first part, while the second part is given over to recording gauges of various types.

Centrifuges.—A new catalog just issued by the International Instrument Company describes the centrifuges manufactured by that concern. The machines are electrically operated, being built in combination with motors. Several of the chemical ends enumerated to which the machines can be put are to dry crystals for rapid production of chemically pure salts, to hasten settling of precipitates and thus avoid oxidation, to extract rapidly essences of compounds from drugs, and to refine sugar. The centrifuges vary in sizes, many being very moderate in price. Accessories are listed in the latter part of the booklet.

Slow-Speed Chilian Mills.—In the fourth edition of their catalog, which was recently issued, the Lane Slow-Speed Chilian Mill Company, of Los Angeles, Cal., print a general article on the use and operation of slow-speed mills. Following this come a detailed description of the company's product, a series of letters from actual operators, and a department of tables and other useful information.

Lava.—The material known as "Lava" and familiar to most people on account of its very universal use in gas tips and burners, is the subject of an instructive booklet issued by the American Lava Company, of Chattanooga, Tenn. The substance is not, as might be inferred, of natural volcanic origin, but is the mineral talc $H_2Mg_3Si_4O_{12}$. It is machined while soft in its natural state and through subsequent baking at a temperature of about 2000° Fahr. it attains its familiar hardness.

Gas-Burning Appliances.—An interesting bound volume of bulletins relating to gas-burning appliances has been recently issued by the Improved Appliance Company, of Denver, Colo. Besides listing the burners and ovens manufactured by the concern, it contains as well much useful data, including tables of melting points of various substances, heating values of gases, boiling points, cubic feet of gases to the pound, approximate water capacity and specific heats. There are also notes on the properties and uses of gases.

Coal Briquetting Machinery.—From the Mashek Engineering Company, of 90 West Street, New York City, comes an extremely well-arranged catalog describing plants and machinery, together with a brief discussion of processes and cost of manufacture. In a section dealing with the possibility of briquetting without binders, it is stated that there is no coal in the United States that can be handled in this way and give a commercially successful article. It is also said that the expenses of plants operating without the use of coal-tar pitch are higher than those of plants briquetting the same fuel with the use of the pitch binder.

The Toledo Electric Welder Company moved its offices from Toledo to Cincinnati on Feb. 4 and is now located in a new factory at Knowlton and Langland streets, Northside, Cincinnati, Ohio. The building is fully equipped with the best and most modern tools necessary for the building of their line of welding machines, the entire plant being motor driven. A 75-kw, single-phase, alternating-current generator supplies the power for testing the welding machines up to their full rated capacity. The shops are lighted by a motor-driven direct-current generator and mercury lights are largely in evidence. A night force will be put on at once to take care of the deliveries promised.

Leadite Melting Furnace.—A folder describing a furnace just devised for melting leadite has been issued by the Leadite Company, Land Title Building, Philadelphia, Pa. The furnace has been designed with special regard to safety, and as it uses gasoline for fuel, it saves much time in pipe jointing work when compared with a charcoal-burning furnace. It will melt 50 lb. of leadite or 325 lb. of lead.

Bleachery.—The Cluett, Peabody Company of Troy, N. Y., are planning to erect, at Cohoes, N. Y., a bleachery to work in conjunction with the shirt and collar manufacture.

The Metallic Purification Company is planning to erect a plant at Chattanooga, Tenn., which will cost approximately $1,000,000 and will employ 1,500 men. It is stated that the principal outputs of the plant will be alum and aluminium. The by-products will depend on the chemical analysis of the clays used. The information so far obtainable is meagre.

The American Oxygen Company of Philadelphia, Pa., was wrongly stated in an article in our last issue to be the successors of the American Ferrofix Brazing Company. The American Ferrofix Brazing Company is still in existence and the American Oxygen Company has no connection with it whatever.

Mines Census.—The Geological Survey and the Census Bureau have entered into a joint arrangement by which the Survey is relieved of the collection of statistics of the annual production of minerals for the year 1909. That work is, by the agreement, merged in the Census Bureau's activities under the Thirteenth Census act, which requires a census of mines and quarries for 1909. Consequently, the Survey will not this year send its own schedules directly to the mine and quarry operators. The Census Bureau's general and supplementary schedules relative to this branch of its decennial work include the inquiries in which the Survey is interested and such other data as may be necessary for the latter's reports will be furnished the Survey by the Census Bureau. The schedules will be collected by the Census special agents and enumerators. The co-operative arrangement was in recognition of the necessity of uniformity in the compilation of the statistics, the elimination of duplicate work and inquiries, and the desirability of economy in the collection of the required data.

The Dorr Cyanide Machinery Company has been incorporated with J. V. N. Dorr as president and offices at 728 Equitable Building, Denver, Colo. This was made necessary by the increasing business in Dorr classifiers and Dorr continuous thickeners, and incidentally permits Mr. Dorr to devote more time to his professional work as metallurgical engineer. An interesting application of the Dorr classifiers and Dorr pulp thickeners is noticed in an article in this issue on a silver cyanide plant in Mexico.

Electrical Mining Equipment.—A publication of interest to electrical engineers engaged in mining has recently been

issued by Crompton & Company, Salisbury House, London, E. C. It contains about 50 illustrations of plants and apparatus typical of the methods used in the supply and utilization of electricity in mines, a subject to which, as demonstrated by the extensive list of mines in which Crompton machinery is used, the company has given considerable attention.

Iron and Steel Activity in France.—Great activity is noted in the iron and steel manufacturing districts in France. This is due in a large measure to the placing of orders for 1000 cars for the state railroads and 2300 cars for the Paris-Lyons Railroad.

National Association of Cement Users.—The annual convention of this association has been held at Chicago, Ill., February 21-25, 1910. In addition to the regular committee reports and topical discussions a list of papers of general interest will be presented.

Carnegie Relief Fund.—The relief fund created by Andrew Carnegie for employees of the Carnegie Steel Company disbursed $200,545 in accident and death benefits and pension allowances in 1909, which is about $10,000 less than the amount paid out the previous year. This makes a total of $1,540,086 disbursed since the relief fund was instituted in 1902.

Iron Production and Consumption.—"The most distinctive feature in the iron trade of the world in the past year," the London *Statist* declares, "has been the marked contrast between the activity in the United States and the lethargy in this country. In truth, the consuming capacity of the American furnaces beyond the American sources of supply of the mineral presents one of the problems of the trade—or presents it again in a vivid form, for it is not a new one—namely, the future supply of the world's iron."

Cement Companies Merged.—By a merger filed with the New Jersey Secretary of State, on Jan. 22, the Cement Manufacturing Company, with a capital stock of $2,000,000, was absorbed by the Alpha Portland Cement Company, which has works in Warren County. The Alpha Company had a capital stock of $6,000,000, of which $2,000,000 was outstanding. The capital stock of the consolidated corporation is $10,000,000, divided into $8,000,000 common and $2,000,000 preferred, the latter bearing 7 per cent cumulative dividends. The officers of the new concern are: President, Arnold F. Gerstell, Easton, Pa.; vice-president, John M. Lockhart, Pittsburgh, Pa., and secretary-treasurer, Gabriel S. Brown, Easton, Pa.

New Engine Ordered.—The Sapulpa (Oklahoma) Steel & Iron Mills have recently placed an order with the Allis-Chalmers company for a 28-in. x 48-in. non-condensing, heavy-duty rolling-mill engine.

New Mining Equipment.—The mining engineering laboratories at the Massachusetts Institute of Technology have recently installed an Allis-Chalmers feeder and a Richards pulsator jig for experiments on ore concentration. This latter apparatus was invented by Prof. Robert H. Richards last year and it has proved of great value. In the mining department the following changes in assistants were made for the current scholastic year: F. Jaeger succeeds L. A. Dickinson; T. G. Chapman succeeds L. D. W. Bender; H. R. Batcheller succeeds C. A. Gibbons, and E. T. Almy has been appointed.

Water Turbines.—The Dayton-Globe Iron Works Company, of Dayton, Ohio, have recently issued catalogs on their "New American Turbine" for the development of water power. The turbines are of the reaction type, vertical or horizontal, and according to requirements are furnished with either balanced flutter, wicket or cylinder gates. Two classes of wheels are made: those for low head from three to fifty feet, diameters from ten to sixty inches, and outputs up to 2363 hp; and those for a high head of fifty to two hundred feet. The largest turbine listed operates with a two hundred foot head and a seventy-two inch wheel and delivers 6784 hp at a speed of 179 to 238 r.p.m. and a discharge of 22,380 cu. ft. per minute. Head gate hoists and gearing work for the wheels, also beating and washing engines and wood pulp grinders are included in the output of this company. The increasing hydroelectric installations among the mining and metallurgical plants of the West present a large field for water turbine equipment.

Salt Industry in Italy.—In Italy the salt industry is entirely in the hands of the government, it being a monopoly utilized as a means of taxation for raising revenue. The importation or production of salt by private individuals is prohibited, and it is sold to the public only in special shops where postage stamps and tobacco are offered for sale. All the salt produced in Italy comes from sea water, evaporated at the works on the islands of Sardinia and Sicily, and at Volterra in the Province of Pisa. The government both imports and exports salt. In 1907 the imports were 51,604 and the exports 99,191 tons. In 1908 the imports were 42,610 and the exports 85,489 tons. Salt was exported to the United States to the amount of 15,590 tons in 1907 and 7,871 tons in 1908.

Glass Manufactory to Rebuild.—The Muncie (Ind.) Glass Manufacturing Company has decided to rebuild its works, recently destroyed by fire, at an estimated cost of $70,000.

Transite Asbestos Wood.—A booklet describing one of their products, "Transite Asbestos Wood," has been issued by the H. W. Johns-Manville Company, of New York City. This material is mineral in character, being made from asbestos fiber and binding cements. It has the same physical characteristics as ordinary wood, except that it is harder and takes a higher polish. Among the advantages urged for this product are its adaptability to manipulation by means of wood-working tools, its fiber strength under transverse loads of 3500 lb., and its absolutely fireproof qualities, it having withstood the most severe tests by fire without being warped, distorted, or weakened in any way. The manufacturers specially recommend its use for flooring, sheathing, partitions, fire doors, fireproof cabinets and gages. A special form of the product, called "Ebony Asbestos Wood," is made to combine high electrical insulating capacity with its fireproof properties. It is somewhat similar in structure to the regular product, but it is saturated with a special insulating compound. When finished it resembles ebony. For example, it may be used for switchboards, panel boards, switch and fuse bases, insulating barriers, duct linings, car-floor linings, electric heater insulation, and rheostat tops.

Personal.

Mr. **F. A. S. Andrew** has joined the firm of E. A. Herbert & Company, Ltd., of London, England, as a director. He will supervise particularly the departments dealing with spiegeleisen, ferro-manganese, ferrosilicon, silico-speigel and other alloys, together with manganese, manganiferous iron and other ores. For the past 20 years Mr. Andrew has been associated with the Pyle & Blaina Works, Ltd.

Mr. **W. G. Bringham** has been appointed manager of the new tin plate plant of the Phillips Sheet & Tin Plate Company, at Weirton, W. Va. He was formerly manager of the American Sheet & Tin Plate Company.

Mr. **Fred H. Daniels** has been decorated by King Gustav of Sweden with the Cross of Knighthood of the Northern Star in recognition for courtesies extended to Swedish engineers in this country. Mr. Daniels is chief engineer and a director of the American Steel & Wire Company.

Mr. **A. E. Drucker** has been appointed consulting metallurgist of the Oriental Consolidated Mining Company in Korea.

Mr. **William E. Ellis** has left for Mexico and has again taken charge of the Guebeshe Mill at Ocotlan, Oaxaca, Mexico.

Mr. **W. Spencer Hutchinson** is arranging for the installation by the Vulture Mines Company of a cyanide plant designed by Mr. S. V. N. Dorr.

Mr. **J. P. Jennings**, district superintendent of the Pennsylvania Coal Company, has been chosen president of the Scranton Mining Institute for the ensuing year.

Mr. **Robert Kann**, consulting chemist to the Raritan Copper Works, Perth Amboy, N. J., has opened at 24 Cliff Street, New York City, a commercial laboratory, making a specialty of metallurgical analysis and research.

Mr. **Julian Kennedy** has been appointed engineer to supervise the erection at Buffalo of a new blast-furnace plant for the Rogers-Brown Iron Company.

Dr. **C. Offerhaus**, known to many of our readers through his connection during the past few years with several metallurgical companies of this country and with Columbia University, is now connected as metallurgical engineer with Messrs. Paul Schmidt & Desgraz, Prinzenstrasse 1a, Hannover, Germany.

Mr. **Leopold Salazer** has been appointed secretary of the Mexican Institute of Mining and Metallurgy to fill the vacancy caused by the resignation of Mr. Kirby Thomas.

Mr. **T. I. Stephenson** has been elected president of the Knoxville (Tenn.) Iron Company, succeeding Mr. W. B. Chamberlain, resigned.

Mr. **Thomas R. Stevens** has accepted a position with the Caucausus Copper Company, of Batum, Russia.

Mr. **R. K. Stockwell**, who has recently been with the Steptoe Valley Smelting & Refining Company, in the position of smelter engineer, has resigned that position and is now construction engineer for the United States Smelting, Refining & Mining Company. At the present time he is stationed at Eureka, Utah.

Mr. **Albert L. Waters** has completed successfully the installation of the new pyritic smelter at Mollen, Colo., six miles north of Denver.

M. **André Weill**, of Paris, has been inspecting a number of water-power sites in the vicinity of Ottawa, Canada, in the interests of the Creuzot Steel Company. This is thought to have to do with the contemplated erection of an electric iron-ore reduction and steel-refining plant near Ottawa.

Obituary.

Mr. **James W. Fuller**, president of the Lehigh Car, Wheel & Axle Works, died in Catasauqua, Pa., on Jan. 15.

Mr. **Fayette Brown**, president of the Brown Hoisting Machinery Company, died on January 20, at his home in Cleveland, Ohio. Mr. Brown was born at Bloomfield, Ohio, in 1823. In 1880, with his two sons, Harvey H. and Alexander E. Brown, he organized the Brown Hoisting and Conveying Company, which has since been reorganized, becoming the Brown Hoisting Machinery Company. At the time of his death Mr. Brown was chairman of the Stewart Iron Company and president of the Union Steel Scale Company and the International Chemical Company.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matters and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Electric Furnaces (*Continued*).

No. 652,640, June 26, 1900, Henry N. Potter, Goettingen, Germany.

Resistance type, for forming tubular Nernst-lamp glowers, etc. The chamber and resistor is a tube composed of a mixture of dry electrolytes, e.g., magnesia and yttria, or zirconia and yttria, ground and mixed with paste, tragacanth or starch, and water, to form a dough. Around this tube is a jacket consisting of one of the constituents of the tube, e.g., magnesia or yttria, or some other material inert or non-injurious to the tube, e.g., thoria. The jacket is baked on the tube in a porcelain kiln. Then a heating-conductor is wound about the furnace, or about a tube of insulating material, talcite, surrounding the furnace. Platinum terminal wires are attached to the ends of the inner resistor tube. The composite tube is heated by gas to such temperature that the inner tube carries current. Upon the first electrical heating both tube and jacket crack. The cracks are filled with a paste of similar material. Several such patchings may be necessary. The jacket serves as a non-fluxing support for the cracked inner tube, having small electrical conductivity. The wire winding serves in use to bring the tube resistor to the temperature requisite to cause it to act as a solid electrolyte and heating resistor.

654,463, July 24, 1900, Henri Leleux, of Paris, France.

"Resistance" type. A furnace especially for the production of calcium carbide, comprising a pot mounted on a carriage or suspended from traveling pulleys, constituting the lower electrode, and an upper electrode adjustably depending from a fixed support. The pot has a flat hearth of carbon blocks and metal sides and casing. The hearth is partially subdivided by a horizontal insulating layer of non-conducting concrete, to concentrate the resistance-heating action of the electric current, passing upward from the metal bed-plate beneath, to the front portion of the hearth, near the tap hole. The metal casing automatically makes contact with an electric main when the pot is moved into place. The pot is surrounded on three sides by walls having openings and passages leading to a chimney, causing a down draught of cool air around the pot. The depending upper electrode consists of four square carbon bars or cores, spaced apart and imbedded in a coked mass of crushed carbon and tar, protecting the cores from air. The resistance of the coked mass is comparatively high, largely restricting the heating effect of the current to the cores. The electrode is cooled by the current of air passing downward around the pot. The upper electrode is adjustably supported by a chain and is connected to two sets of cable-mains. Contact with the cores is made by thin copper plates, which may be silvered, compressed against the inner faces of the upper ends of the carbon cores by wedges and screws.

654,467, July 24, 1900, James Mactear, of London, England.

Resistance furnace, for heating a mass of wood charcoal or other catalytic substance. The heated mass is employed to convert a mixture of ammonia and carbon monoxide into ammonium cyanide. The furnace chamber is oblong and has sides of porcelain, closed at the top and bottom by removable horizontal plates. Inlet and outlet gas mains lead through these plates. The chamber is heated by a series of platinum resistance-coils, wound on vertical refractory rods and mounted in refractory tubes depending from the cover of the chamber, giving a uniform temperature throughout the charcoal.

655,779, Aug. 14, 1900, William Smith Horry, of New York, N. Y.

A uniform current at constant voltage is maintained by moving the furnace electrodes relatively to each other or to the furnace chamber, which may be fixed or movable. The furnace shown is of the Horry wheel type, two electrodes of opposite polarity depending into the wheel receptacle at one side. The wheel is rotated by a gear on its shaft, driven by a worm and electric motor. A two-phase motor is shown, which may be driven in either direction by two switches, employing mercury cups. Pins which enter these cups are carried by a tilting lever. Gravity normally tilts the lever to make contact with one set of mercury cups. As the current in the furnace mains increases, it acts through a transformer surrounding one main and a solenoid energized thereby to tilt the lever and close the other mercury cups, reversing the motor and moving the wheel receptacle in such direction as to decrease the current. The current from the transformer may actuate the motor switches through an electro magnetic relay, instead of directly. The motor may be direct current, or a steam, air or hydraulic engine may be used.

655,780, Aug. 14, 1900, William Smith Horry, of New York, N. Y.

A modification of the preceding furnace-control mechanism. A slow, even movement of the current-regulating element of the furnace is undesirable, causing the mixture in the furnace to form an arch which delays response to the regulation. The improved mechanism is intended to give the regulating element a quick, jerky movement, causing the mixture to fall at once into the zone of reduction. The mechanism shown is a long bar, extending past a number of furnaces of the Horry wheel type, and continuously reciprocated. Connected to the bar at each furnace is a vertical pivoted lever, the upper end of which carries two pawls, faced in opposite directions and respectively engaging two ratchet-wheels on a shaft geared to the furnace. The pawls are weighted to normally remain out of engagement with the ratchet-wheel, but a solenoid is arranged to magnetize each pawl and cause it to engage. The solenoids are respectively energized by switches electro-magnetically controlled by the furnace current, as in the preceding patent.

656,600, Aug. 21, 1900, R. Doolittle, of Chicago, Ill.

Arc type. The furnace used for manufacturing calcium carbide in accordance with the process of patent 656,599. The furnace is a tall, narrow stack, having a hopper and feed-screw at its upper end. Burners for gas or oil open into the top of the chamber. Superposed pairs of opposed electrodes pass through the side walls of the stack, near its middle. A gas-exhaust pipe leads from the lower part of the stack. A removable receptacle closes the lower end of the stack and receives the carbide; or the carbide may be tapped out. In a modification, the lower end of the stack is surrounded by a cooling jacket or coil, and air is injected into the bottom of the stack to cool and granulate the carbide. Grates are shown to subdivide the carbide into small streams as it flows downward to the blast.

656,930, Aug. 28, 1900, Wilhelm Borchers, of Aix-la-Chapelle, Germany.

Arc or resistance type, especially for the manufacture of calcium carbide. The furnace is a vertical or inclined stack having a hopper at its upper end and opposed electrodes passing through its sides. The lower portion of the stack is surrounded by a water-jacket, cooling the product below 400° C. The jacket may be used as a steam boiler for running an engine. The contents of the furnace are gradually removed at the lower end, allowing the pig or carbide to descend. Portions are then broken off by chisels, passing through openings in the walls. In the inclined type of furnace, a toothed roller extends through the lower end, engaging and pulling the carbide downward. Surrounding the feed-hopper is a gas outlet chamber containing peat carried on a perforated bottom, which acts to filter the escaping gases and prevent their carrying away combustible dust.

(*To be continued.*)

BOOK REVIEWS.

A Text Book of Ore Dressing. By Robert H. Richards, S.B., LL.D., assisted by E. S. Bardwell and E. G. Goodwin. 702 pages, 374 illustrations. Price, $5 net. New York: McGraw-Hill Book Company.

Our German masters in technology have an expressive term whose exact equivalent does not exist in English. They distinguish the "Lehrbuch" from the "Handbuch"; the former is the *teaching* book, the latter the *reference* book. Professor Richards has made this separation in the realm which he has made almost his private domain. His Ore Dressing is inimitable, unmatched in its thoroughness, but for that very reason unsuitable for teaching the subject. Messrs. Bardwell and Goodwin have condensed the matter from the larger four-volume work on Ore Dressing, and did the actual writing of this book to which Professor Richards contributed only the general outline, and the storehouse from which all the material was extracted.

Ore Dressing is mostly a concentrating operation, to render the valuable material more available and to facilitate its extraction and utilization. We may therefore say that one of the most useful contributions which Professor Richards has made to this subject, comparable perhaps to anything else he has accomplished in actual value to the profession, is the operation by which, with a concentration ratio of 4 to 1, the present volume has been extracted from its immediate predecessors and progenitors. The result is a "concentrate" whose value to students, teachers, learners, laborers, and masters in this field is almost inestimable. Its completeness and accuracy disarm criticism. Its parts are splendidly balanced, the treatment is equable and judicial, and altogether it is a "Lehrbuch" in the best sense and quality of that word.

* * *

Welding and Cutting Metals by the aid of Gases or Electricity. By Dr. **L. A. Groth**, Consulting Engineer. Cloth, 281 pages, and many illustrations. Price $3.00. D. Van Nostrand Company, New York, 1909.

This work contains a full account of the various processes mentioned in the title, particularly as practiced abroad. There are introductory notes on the gases employed and descriptions of the apparatus for using them are very detailed. A comparison is drawn between the oxy-hydrogen and oxy-acetylene methods, and the burners or blow-pipes suitable for each are illustrated and the construction shown. The welding of aluminium is given a special chapter. In this no mention is made of Mary W. Emme, who secured a U. S. patent for welding this metal, antedating Heræus.

The Goldschmidt aluminothermic welding process is accorded a considerable space. Particular attention is paid to electrical welding devices, those of Thomson being prominent, and numerous illustrations are given of the apparatus used. The subject of welding marine boilers forms a chapter by itself, as also the cutting of metals by the blow-pipe. There is a chapter on reports of the efficacy of acetylene welding, and a final chapter on legislation.

The work is attractive and well printed. The style, while interfered with by many extracts from reports and trade descriptions, has a slightly foreign tinge.

* * *

Solid Bitumens. Their Physical and Chemical Properties and Chemical Analysis, Together with a Treatise on the Chemical Technology of Bituminous Pavements. By **S. F. Peckham,** A. M., Chemist to the Department of Finance, City of New York. 8vo, 324 pages, 29 illustrations. Price, $5. New York and Chicago: Myron C. Clark Publishing Company.

A praiseworthy attempt to bring order out of confusion in a very dark corner of chemical technology.

Part I (89 pages) deals with the natural history of the bitumens, their history, distribution, derivation and classification.

Part II (172 pages) is the principal portion of this book, dealing with the chemistry of the bitumens, in eight chapters. The principal topics are the methods of ultimate analysis, proximate analysis, technical analysis, special tests, and the testing of auxiliary substances, such as street mixtures, cements, concretes. A person who knows little of the subject will find here a great store of information, carefully and systematically collated; the expert who knows almost all about the subject will doubtless find the presentation valuable for reference and discover some original ideas contributed by the author.

Part IV (19 pages) deals rather too briefly with the physical properties of the bitumens. In our comparative ignorance we had thought the physical properties would have been given nearly as extensive a consideration as the chemical properties;

certainly a larger part of the usefulness of the bitumens finds its basis in their characteristic physical properties.

Part V (38 pages) is a brief presentation of the chemical technology of bituminous streets, and is considerably below the level of the rest of the book. This subject is handled so well in Dr. Clifford Richardson's "The Modern Asphalt Pavement" that Mr. Peckham would have saved himself trouble and ended his book more fittingly by simply giving this reference, and not have run the risk of spoiling the good impression made by the rest of his book.

While the author's style is here and there stiff and his treatment at times controversial, yet his writing is almost always interesting and his arguments instructive, even when they fail of being convincing.

* * *

Beet Sugar Making and its Chemical Control. By **Y. Nikaido**, B.Sc., M.A. Cloth. Price, $3. Easton, Pa.: Chemical Publishing Company; and London, England: Williams and Northgate.

In the preface of this book it is stated that "the aim of this work is to aid those who are starting their career in the beet sugar manufacture, but lack systematic training in the technique thereof."

The preface likewise offers a list of references used by the author in the preparation of the book. These are, many of them, of elementary character, such as should be available either in a private or public library to any one, who would venture to enter the beet sugar industry either as employer or employee. The industry requires trained men, and has little tendency toward the training of men from the start. Our chief criticism of the book is that it contains so much that is elementary and inadequate to the accomplishment of the purpose intended.

The first four chapters might well be eliminated and this is also largely true of Chapter V.

For young employees in the laboratory, inexperienced in beet-sugar analysis, which is possibly the class referred to by the author in his preface, the descriptions of the apparatus and analytical methods in Chapters VI to IX inclusive, will be of some use, and they will be useful also to the laboratory director because it will obviate the necessity for much elementary instruction. Otherwise the work seems of doubtful value.

The book is well made, excellently printed and bound, contains a good table of contents and list of illustrations, and a well prepared index, the latter so often wanting in technical works.

The book also contains six tables which may prove useful in some laboratories, but which in presence of the valuable books of Kent, Spencer, Biedermann, Stammer, Stohmann, and Classen, which should form part of the equipment of the laboratory of every beet-sugar works, are entirely superfluous and need not have been copied.

* * *

A Course of Qualitative Chemical Analysis of Inorganic Substances, with explanatory notes, by **Olin Freeman Tower**, Ph.D., 83 pages. Price, $1. Philadelphia: P. Blakiston's Sons and Company.

In the opening paragraph of the preface of this book the author properly remarks "Some apology is necessary for the appearance of another text-book of Qualitative Analysis." And he further properly remarks "most of the briefer treatises on this subject are entirely inadequate in the treatment of the subject from the modern standpoint and in lack of precautionary directions which are necessary to secure delicacy of practice."

What the author says is intensely true. Most of the "briefer courses" of qualitative analysis are mere "short cuts" to success, and in this class of work as in every other the short cut to success generally ends in failure.

This should not be true, by any means, of the work before us. It is up to date in every respect. It is practically an application of the modern theories and laws of physical chemistry to chemical analysis, and it is entirely new.

In the introduction are discussed briefly dissociation, ionization, reversible reactions, reactions between ions, equilibrium and the solubility product, hydrolysis, amphoteric electrolytes, the electro-motive series and oxidation and reduction; briefly, the chief principles of physical chemistry.

Then follows "Directions for Laboratory Work" in application of the principles set forth and described in the introduction. These begin with "basic" analyses or, in less modern parlance, properties of and tests for bases and the separation and detection of these substances, followed by sections or chapters on "acid" analysis and dry substances.

In the basic analysis the grouping of the elements is but slightly different from that adopted in the older text-books on the subject.

The seven groups of the author are as follows: Silver Group, Copper-Tin Group, Iron Group, Zinc Group, Calcium Group, Magnesium Group and Potassium Group.

In the discussion of the several groups in basic analysis the author treats each one in the following order, preliminary tests, precipitation, notes on precipitation, analysis and notes on analysis.

In the Tin Group the author adds a brief chapter on interfering substances and notes thereon.

In acid analysis he establishes three classes: the sulphuric acid group, the halogen group, and the nitric acid group; and in this division he follows a method of treatment somewhat different from that used in the basic division. He makes two brief chapters, the first on preliminary tests, and the second on speed tests.

The preliminary tests seem to show the presence or absence of ammonium and sodium, and the condition of reduction of the compounds of iron and of the tin salts which may be present.

A page of notes following the preliminary tests calls attention to precautions to be observed and oversights which may occur, as well as reactions which may be produced in the operations and which may affect the ultimate result.

Following the matter on preliminary tests are chapters devoted to the separation of each of the groups respectively and the analysis of the group separated, and each separation and analysis is accompanied by a page of notes relating to the procedure. This arrangement of the systematic analysis is novel, but it seems effective and should serve well in laboratory works.

A brief chapter is likewise devoted to analysis in the dry way, corresponding with the usual course of blowpipe analysis.

The book proper closes with a chapter on the preparation of solutions, and here the author offers instruction in the preparation of solutions and of solid substances for examination; first for basic analysis, and second for the acid analysis.

An appendix is added giving a table of reagents in solution, showing specific gravity of the solution, concentration per cent, and approximate normal concentration. A few paragraphs on special methods for preparing certain solutions, which will prove useful in every laboratory, a table of degree of dissociation of electrolytes, and a series of optional methods for treatment of the several groups respectively, are also added.

On the front cover lining is a table of atomic weights of the principal elements and on the back cover lining is a solubility table. The book is also of convenient form and size for use on the laboratory table.

The book is well worthy of the considerate attention of instructors in qualitative analysis and will doubtless find a place in many of the laboratories of instruction throughout the country.

Pittsburgh Meeting of the Americal Electrochemical Society.

Pittsburgh, the center of the iron and steel industry, a center of chemical engineering activity, and the home of one of the largest electrical manufacturing companies of the world, will be the place of the annual convention of the American Electrochemical Society, to be held in the beginning of May. The selection of Pittsburgh was a logical one after the great success of the symposium of papers on the electrometallurgy of iron and steel, at last year's annual meeting in Niagara Falls. The electric steel furnace is no longer considered with suspicion or contempt by the practical iron and steel man; it is now being recognized as a very useful adjunct to Bessemer-converter and open-hearth steel plants and it is evident that it will be in extended use before many years in steel works all over the country. Among the visits which have been arranged for the convention, there are two to steel works where electric refining furnaces are in operation and in every other respect the very full program of excursions and social functions, printed elsewhere in this issue, is likewise extremely attractive. The program of papers, which has not yet been announced, will, without doubt, be no less interesting. The Pittsburgh meeting should become another milestone in the career of the American Electrochemical Society.

The Decomposition of Carbon Monoxide in the Presence of Catalytic Agents.

A positive definition of a catalytic agent seems difficult. When a substance simply by its presence (without undergoing any change or without participating in the reaction at all) starts a reaction that would otherwise not go on by itself, we call it a catalytic agent. Ostwald defines in general a catalytic agent as one that changes by its presence the velocity of a reaction without entering into the reaction. Perhaps we should add that we speak of a catalytic agent only, if we do not understand the rationale of its action. If we place a well amalgamated pure zinc rod into a sulphuric acid solution it will not dissolve, or only slowly; if we wind a small piece of platinum wire around the zinc rod, the zinc at once dissolves with strong evolution of hydrogen. Of course, we know that we have here a short-circuited galvanic cell, and because we understand the reason, we would hardly speak of the platinum as a catalytic agent in this case. It is the subjective element of mystery that should find expression in a complete positive definition of a catalytic agent. While contact processes are mysterious, they are extremely important and have come very much to the front. A very small amount of catalyzer often exerts a very great influence on the reaction.

* * *

Dr. Zimmermann's paper, printed in this issue, on the decomposition of carbon monoxide in the presence of catalytic

agents at certain temperatures, will be found very interesting from a purely scientific standpoint and with respect to the reactions in the blast furnace. He shows that carbon monoxide will decompose into elementary carbon and carbon dioxide at temperature near 300° C., with cobalt, for instance, as catalyzer. The reaction is still more interesting and curious if iron is used as catalyzer at 445° C. Iron first acts as catalyzer, decomposing CO into CO_2 and C. It is then oxidized according to the equation $Fe + CO_2 = FeO + CO$. The CO is again decomposed by catalytic action and so on. Iron is here not a pure catalizer, while carbon monoxide appears in the peculiar role of an oxidizing agent for iron.

Zinc and Lead Pigments.

In most processes of ore reduction every effort is made to avoid the production of dust and to prevent any oxidation of the valuable constituents of the ore. It is true that volatilization processes have been devised from time to time in which the metallic constituents are driven off as a volatile salt such as the chloride, but they have never proved successful. Lead and zinc ores, however, have been found amenable to volatilization as mixed oxides and sulphates, and their treatment in this manner may become an important adjunct to the pigment and paint industry. The extended use of zinc as a pigment is interesting in view of a tendency toward the proscription of lead in the customary form of white lead, or basic carbonate. This has been especially true in France and Belgium, where laws adverse to the lead industry have been passed. This matter is more fully referred to in an abstract in the Synopsis in this issue. The manufacture of zinc oxide in the United States dates from 1855. Simply stated, the process consists in burning in a blast furnace of suitable construction a mixture of zinc ore and coal or coke, recovering the volatilized zinc oxide in bag houses. Application of the same principle has been made to lead ores and to mixed zinc and lead ores, giving a basic lead sulphate and a mixture of zinc oxide and basic lead sulphate, respectively.

* * *

It will be apparent that the direct production of clean pigments in a process no more complicated than this would be a decided improvement over first reducing the metal from the ore and then reconverting it into pigment. Furthermore, the treatment of a mixed sulphide of zinc and lead is of great value, as it obviates not only the necessity of reduction, but of previous separation of the minerals and this is frequently difficult and never accomplished without loss. Since most of our ores of zinc and lead are sulphides, and therefore amenable to this process, it would seem to be a matter of less moment whether the manufacture and use of white lead are ultimately prohibited or not. Industry is quick to change to a process which promises both technical and financial betterment and never awaits an act of prohibition to drive it to something new. Perhaps the manufacture of pigment by volatilization of the metal from the ore will prove so much more desirable commercially than the corrosion of the reduced metal, that white lead will be retired without resort to legislation, be it wise or foolish. It should not be beyond the range of possibility that some pigment be found to supersede the basic carbonate of lead, and, indeed, if the advocates of basic sulphate of lead, with or without admixture of zinc oxide, are to be believed, the new pigments may be superior to the old.

* * *

If the process should be feasible and profitable, we have an almost unlimited and suitable ore supply, so that the production of zinc and lead pigments by the new method should be limited only by the demand which can be created for them. It is of no commercial importance whether the pigment is a basic carbonate or a basic sulphate, and a manufacturer would just as soon make one as the other. In any event, the lead industry can only profit by these advances and improvements. As a matter of fact, the production of white lead in the United States has been on the wane. This industry reached its zenith in 1904 when the production was 126,336 short tons. In 1907, which was an off year, it dropped to 111,409 tons and was only 116,628 tons in 1908. Imports also have shown a slight tendency to decrease in that period. The production of zinc oxide, on the other hand, has shown a steady increase since 1897, and when the output of zinc-lead pigment is added to this, a decided increase is noticeable. Imports of zinc oxide have also shown a general upward tendency since 1900.

The Chemical Industries of the United States.

The admirable address delivered by Prof. Charles E. Munroe before the American Institute of Chemical Engineers and of which the first part is published in the present issue, gives an excellent sketch, based on the best statistical data available, of the chemical industries of this country, their present very large extent and the much greater possibilities of the future. Professor Munroe is right in pointing out the difficulty of stating exactly what industries should be considered as chemical. It is, after all, a matter of definition and the popular idea of the term "chemical industries" will adapt itself to the economical development of the future; it will depend on the energy and success with which the chemist and chemical engineer make their influence felt in various industries in an advisory and managing capacity. To mention one instance, the metallurgical works proper were formerly considered as an adjunct to the mine and were managed by mining and mechanical engineers. But with progressing specialization, rendered necessary by the more difficult metallurgical problems to be solved for poorer or more complex ores, it has become practice that a metallurgical engineer is made the responsible head of the metallurgical operations proper. But the sphere of interest and activity of the metallurgical engineer is much nearer to that of the chemical engineer than of the mining engineer. In fact, metallurgical engineers may be considered as a special (and very important and influential) class of chemical engineers in general, just as metals are a special class of chemicals.

* * *

The statistical figures of Professor Munroe (of which a great deal more will be found in the concluding part of his paper to be published in our May issue) are interesting in various respects, but special attention should be called to the figures of the percentage changes of wages, cost of raw materials, and price of products in periods of 5 or 10 years. In estimates of the economical working of a chemical or metallurgical plant these changes should be taken carefully into account; to neglect of analysis of costs may be ascribed many financial diffi-

culties in the electric lighting and railway field. While Professor Munroe's figures show a steady and healthy growth of the chemical industries of this country, they also emphasize the shortcomings. The fact that the value of "chemicals, drugs and dyes," imported into this country in 1908, amounted to $73,000,000, shows vast possibilities of future developments. Further, almost 50 per cent of our total exports in 1908 consisted of material which had not undergone any degree of manufacture whatsoever. Professor Munroe is right in advising to put in this country into manufactured form the raw materials of this country; this should really be part of the policy of the conservation of natural resources. To one special point Professor Munroe draws special attention: We sit back glorying in our country, its wide extent, its rich resources; and we continue to sacrifice the fertility of our soils to the support of older civilizations and remain content, while ranging ourselves with those nations that live solely on their primary resources, since the balance of trade is in our favor. But chemists know that this condition cannot last; the average fertility of the soil has been growing steadily less. The utilization of the soil as a chemical factory is but one of the broad problems with which the chemist has to deal.

* * *

To one point, not mentioned in Professor Munroe's paper, attention may be called here. It is often said and it is perfectly true within certain limits that the chemical industry of this country is an imported industry and that in many respects we are still far behind Europe. This is true, for instance, for the coal-tar industry, which has undergone such an enormous and splendid development in Germany that it will be a long time before this country can hope to reach the same state of development. But in other fields this country has gone steadily ahead and in one special field this country has been the pioneer of a new chemical industry—the electrochemical industry, which in various ways is specifically American. It is characteristic that it was founded by engineers rather than chemists. Whether Dr. Acheson's prophecy will turn out true that this is the dawn of a great electrochemical era, the future will show. But there can be no doubt that electrochemical methods and processes will steadily increase in commercial importance in many chemical and metallurgical fields; and the brilliant success achieved by the electrochemical industries of this country will be a source of inspiration to all American chemists.

Compromise in Smelter Fume Suits.

Judicious compromise is the order of the day in disputes arising from smelter fumes. With the decision of Judge Hunt still fresh in our memories, wherein he dissolved the injunction obtained by the farmers against the Anaconda company in the famous Montana suit, it is gratifying to note that a compromise has been effected between the litigants in a similar case in Shasta County, California. Judge Hunt's decision in Montana was broadly based on the principle of the greatest good for the greatest number. He regarded smelting as of primarily greater importance than agriculture to the Deer Lodge Valley and dissolved the farmers' injunction on the further ground that the smelting company had exhausted all means known to modern technical skill to control the enormous volume of fume which the plant was producing.

While conditions in California and Montana are not exactly comparable on account of the greater magnitude of metallurgical operations in the latter State, a distinctly progressive step has been made in the compromise of the California suit in that the smelting companies recognize both the possibility and advisability of suppressing fume. So successfully have the chemists and engineers of the smelting companies attacked the fume problem during the past two years, fighting for their very existence, as it seemed, that they have improved greatly on conditions as they existed during the Anaconda suits. Hence any plea of inability on the part of the smelters could not avail now. By the terms of the California compromise, the Mammoth Copper Company agrees to equip its plant with neutralizing and bag-house devices for wholly suppressing the sulphuric and arsenious acids now discharged into the air. The scheme to be used will probably be that adopted in Salt Lake Valley on account of similar suits, in which the sulphuric acid is neutralized by zinc oxide and all solid matter filtered from the gases through the bag house. An additional point in the California compromise is that the gases finally discharged into the air shall not contain more than seventy-five hundredths of 1 per cent of sulphur dioxide by volume. This will require the dilution of the gases by admission of large volumes of air. Both parties to the suit are granted the right and privilege to make inspections to see that the provisions of the compromise are carried out. The smelting company was allowed 90 days to carry out its work.

* * *

Referring again to the conditions in Montana, it may be said that the fume question is by no means permanently settled there. An appeal from Judge Hunt's decision is now in the Circuit Court. Whether the smelting company can be compelled to eliminate the fume nuisance or close down is a question. The magnitude of operations at Anaconda gives rise to conditions that can scarcely be appreciated on first thought. The company has taken cognizance of every known method of handling fume and has had to abandon all on account of the prohibitive expense or inefficiency. Wherefore it is not fair to assume that what is an efficient system for a smaller smelter might just as well be adopted at Anaconda. Many months ago the Anaconda company presented to the court an exhaustive report on the technology and cost of various systems for eliminating fume and showed their impracticability as far as that smelter was concerned. Mr. Mathewson, in charge of smelting operations, showed that a spraying system would give an acid mud difficult to dispose of, and the plant would cost $3,000,000. A sufficiently capacious bag house would cost $2,750,000, and entail a daily expense of $1,800. For the freezing system the plant would cost $4,000,000 and the cost of operation would be $10,000 per day. A zinc oxide neutralizing plant, such as is used in Utah and will be used in California, would cost $3,000,000 and require 500 tons of zinc ore daily. Thus, it will be seen that the problem is one of no mean proportions, although it is not wholly beyond the range of expectation that it will be solved, at least, in a measure. In the meantime, other plants are working on various schemes in a commendable effort to avoid conflicts with other local interests, and, perhaps, the smelter fume suit in the West will soon become a thing of the past.

Pittsburgh Meeting of the American Electrochemical Society.

The preliminary program of the seventeenth general meeting of the American Electrochemical Society, to be held in Pittsburgh on May 5, 6 and 7, has just been issued. The hotel headquarters will be at the Fort Pitt Hotel, quite near the Union Station.

On **Wednesday,** May 4, the secretary will be at the Fort Pitt Hotel and members and guests can register and receive badges after 12 m. At 2 p. m. it is proposed, if a sufficient number of members will be present, to make a visit of inspection to the Technological Testing Plant of the U. S. Geological Survey. Special tests of fuels, explosives and other materials of the highest technical interest will be arranged by the engineers in charge. Whether this visit is to be made will depend on the attendance of the members; all who can be present on this afternoon for this purpose should inform, in advance, the secretary, Dr. J. W. Richards, Lehigh University, South Bethlehem, Pa. Final notice as to whether the visit is assured will be given in our next issue.

On **Thursday,** May 5, a meeting of the board of directors will be held at 9 a. m. at the Fort Pitt Hotel to be followed at 10 a. m. by the annual business meeting of the Society, at which the report of the annual election and the annual report of the board of directors will be presented. This will be followed by a professional session in which a number of papers will be read and discussed.

For the afternoon of Thursday, a number of interesting excursions and visits have been arranged as follows: Alternatives: Park Company's crucible steel mills, Carnegie Steel Company's dried-blast plant at Isabella Furnace, Jones & Laughlin's Steel Works (Talbot continuous steel process), Pennsylvania Lead Smelting Company., Nernst Lamp Factory, Oxy-Acetylene Welding Company.

In the evening at 8 p. m. Dr. L. H. Backeland will deliver his presidential address at the Fort Pitt Hotel, to be followed by the reading and discussion of papers of general interest.

Friday, May 6, will be devoted to an all-day excursion, leaving Union Station at 8:30 a. m. and visiting the Allegheny Plate Glass Works at Glassmere, the Westinghouse Electric Works at East Pittsburgh, the Firth-Stirling Works at Demmler (where the Héroult electric steel furnace is in operation), the Carnegie Steel Works at Homestead (where a new type of combined open-hearth and electric furnace is in operation). Lunch will be served on the train; return to Pittsburgh at about 5:30 p. m. Cost of the excursion, $1.50 each.

In the evening at 7 p. m. an informal subscription dinner will be held at the Fort Pitt Hotel, followed by "light entertainment by Section Q."

On **Saturday,** May 7, a professional session for the reading and discussion of papers will be held at the University of Pittsburgh, Grant Boulevard. At 1 p. m. lunch will be taken at the Hotel Schenley.

For Saturday afternoon at 2.30 a general public meeting has been planned, the program being of general interest. It includes addresses on the present status of electrochemical industries (illustrated), on the advantages of Pittsburgh as an electrochemical center, and, by an eminent speaker, on the conservation of natural resources of power. Full details of this meeting, which it is hoped to attract a large audience and to arouse general public interest, will be given later on.

This meeting will be followed by visits to the Carnegie Institute and Museums, Carnegie Technical Schools, University of Pittsburgh, and other points of interest in the vicinity of the Carnegie Music Hall

In the evening members staying in the city will be invited to an "at home" at one of the local clubs.

The above program is subject to modification in any of its details. The final program, including the titles of papers to be presented, will be printed in our next issue.

Ladies are cordially welcomed to the meeting; their comfort and entertainment will be in the hands of a Ladies' Committee, and they are invited to attend the sessions, the dinner on May 6, the luncheon on May 7 and the excursions on May 4, 5 and 7.

A fine program and a highly interesting meeting is assured and the Local Pittsburgh Committee hopes to see a record-breaking attendance at the first gathering of the Society in Pittsburgh.

American Institute of Chemical Engineers.

The summer meeting of the American Institute of Chemical Engineers will be held at Niagara Falls, N. Y., June 22 to 24, 1910.

A prominent feature of the meeting will be visits to the important and interesting chemical industries in this locality.

American Foundrymen's Association.

The convention of the Allied Foundry Associations will be held in Detroit, Mich., June 6-10, 1910. Committees of the American Foundrymen's Association and American Brass Founders' Association are engaged in making the convention the best that has yet been held. An exhibit of mechanical equipment will be an interesting feature and extensive arrangements are being made for visitation of plants. The headquarters of the convention will be at the Pontchartrain Hotel. Information regarding the convention can be secured from Mr. Frank T. F. Stephenson, chairman of the general convention committee, 12-14 West Atwater Street, Detroit, Mich.

Chandler Testimonial.

In our February issue (page 65) we recorded the fact that after a very long period, almost a lifetime, of the most useful activity as head of the department of chemistry and dean of the School of Mines of Columbia University, Dr. Charles F. Chandler will retire from his duties at the end of the coming term, to be appointed professor emeritus of chemistry.

To commemorate this important epoch of his life the following organizations have taken the initiative in planning for a testimonial to be tendered to Dr. Chandler by the chemists of the United States: The Chemists' Club, the Society of Chemical Industry, the American Chemical Society, the American Electrochemical Society, the American Institute of Chemical Engineers and the Verein Deutscher Chemiker.

The form of this testimonial has been arranged, firstly, in form of a banquet at the Waldorf-Astoria, on Saturday, April 30, at 7 p. m. The cost of each dinner ticket will be $5, a sum, which, while not sufficient to defray the expenses, will insure a large attendance. Ladies will be admitted to the galleries and light refreshment served them at a nominal charge of $1 per person.

At this banquet a bronze bust of Dr. Chandler, in heroic size, to be executed by the famous sculptor, Mr. J. Scott Hartley, will be presented to him. This bust will finally be presented to the Chandler Museum of Columbia University. A replica of this bust is to be presented to Mrs. Chandler.

Finally, a Chandler Testimonial Fund will be created for the purpose of purchasing books for the library of the Chemists' Club.

Subscriptions for the banquet and the general expenses of the testimonial are to be sent to the treasurer of the committee of arrangements, Dr. Morris Loeb, 273 Madison Avenue, New York.

Mr. I. F. Stone is the chairman and Dr. Charles F. McKenna, 50 Church Street, New York, the secretary of the committee.

International Congress of Inventors.

The "International Congress of Inventors" was established in 1906, with headquarters in Rochester, N. Y., and incorporated in 1907. One of the objects of the congress is "to endeavor to establish a standing for a United States patent independent of any court action." Mr. George F. Gallagher is the president, Mr. Ralph T. Olcott the secretary. The headquarters are at 123-125 Ellwanger & Barry Building, Rochester, N. Y.

Under the auspices of the congress a "national convention of inventors" and exhibition of patents and models will be held at Rochester, N. Y., from June 13 to 18, 1910.

The Iron and Steel Market.

Each year in the American iron trade has shown a distinct color, and the current one is proving no exception, presenting a color so novel as to perplex the majority. We have had the spectacular boom of 1899, the quick reaction of 1900, the steady growth in prices and demand in 1901, the feverish activity of 1902, the reaction of 1903, the melancholy dullness of 1904, the sharp revival of 1905, the sustained improvements of 1906, the storm of 1907, the much talk and little performance of 1908, and the stupendous recovery of 1909. Through all these vicissitudes there has been created the machinery for doing an enormous amount of business with a minimum of noise and confusion, but unprepared by recent example for such performance, the iron and steel trade stands confused and is alternately looking for improvement and fearing a reaction, at a time when production of both pig iron and steel is at the highest rate ever recorded, passing by 20 per cent the average of the best previous calendar year, while close to 100 per cent of the tonnage produced is passing quietly into consumption and the small tonnage which may possibly be accumulating in the hands of mills and jobbers is bound to be distributed promptly on the appearance of really spring weather conditions.

This line of treatment may seem fanciful, but the solid ground for it can be shown by analysis of history. One must, in fact, go back to 1890 to find similar conditions. Then, despite the fact that the industry was much smaller than now, identical conditions were presented. There had been a reaction in 1887, a dull period in 1888, and a somewhat feverish recovery in 1889. In the early months of 1890 conditions were precisely similar, at all comparable points, with the present. Tonnage was enormous according to the then scale, yet the market moved doubtfully and prices showed a slight receding tendency. Throughout that year the market doubts continued, and yet it ended by disclosing a pig iron output 21 per cent in excess of the best previous record. If like conditions produce like results, we shall find, for this year, a maintenance of the present production rate, without realizing where all the demand comes from, and a substantial maintenance of prices, though with occasional slight recessions. Hitherto in recent years when the demand for iron and steel reached new tonnage proportions it strained the existing capacity and resulted in delayed deliveries and advancing prices; at this time there is no strain upon productive capacity, for it has been very largely increased since the last test, in the first 10 months of 1907.

Late in February a slight improvement occurred in demand for finished steel products, which was continued until nearly the middle of March. The tone of the market improved concurrently, and confident predictions were made of a continuance of the improvement. About the middle of the month the market experienced a slight chill, from which in due course it will no doubt recover.

Pig Iron.

The theory that because Lake Superior ores were advanced 50 cents for the coming season pig iron for second-half delivery would necessarily be higher than for first-half delivery was abandoned when, early in the month, the Westinghouse Electric & Manufacturing Company bought foundry iron for second-half delivery, 5000 tons for its Allegheny works, in Pittsburgh, at $16.50 delivered, and 10,000 tons for its Cleveland works at $16.75 delivered. The Pittsburgh iron was at a lower price than had been done for early delivery, while the Cleveland iron was at no more than a trifle above the ruling market for early delivery. In other districts pig-iron business was done at slight recessions from former prices, and Southern iron was done at $12.50, Birmingham, for May and June delivery. While the pig-iron market may not show a condition of total depravity, it is at least not in good form that when Northern iron failed to show a higher price for second half, on account of the advance in Lake ores, the Southern pig-iron industry, which is self-contained, should show lower prices for prompt than for second-half delivery, yet such is the case. Prices at valley furnaces (90 cents higher delivered Pittsburgh) are substantially as follows: Basic, No. 2 foundry and malleable, $16 to $16.25; gray forge, $15.25 to $15.50; Bessemer, $17.75. The price on Bessemer represents a decline of 25 cents, early in the month, brought about by sales of 10,000 tons to the Cambria Steel Company and 7000 tons to the Lackawanna at a nominal price of $18, valley furnace, but with an allowance of three months' interest.

Steel.

A large tonnage of billets and sheet bars has been moving on old contracts, while new business has been very light. There is occasional demand for open-hearth billets, particularly small sizes, which are scarce. Quotations remain at $27 to $27.50 for Bessemer billets, $27.50 to $28 for open-hearth billets, $28.50 to $29 for sheet bars and $33 for rods, all f.o.b. maker's mill, Pittsburgh or Youngstown districts. The Carnegie Steel Company has put in operation the last of the four 55-ton open-hearth furnaces at the Homestead Steel Works on which construction was commenced last summer. This gives the Homestead works 64 open-hearth furnaces and one electric furnace.

Finished Products.

Prices in the main show no change, but one or two products have trended slightly to weakness. Iron bars are a trifle easier in the Pittsburgh and valley districts, but are still quotable at $1.65 to $1.70, Pittsburgh, while the Chicago market has declined $1 a ton to $1.50, Chicago, and the St. Louis market has experienced a rather sharp drop of $2 a ton, sales being made at $1.40 at mill, St. Louis district. Shading of a dollar a ton has appeared in corrugated sheets, flat sheets being well maintained. Wire products show less shading than a month ago. Line pipe is being cut rather freely, while merchant pipe is nominally unchanged. While the price of $1.55, Pittsburgh, on plates and shapes remains for the Pittsburgh and Western markets, the shading of a dollar a ton from this basis continues in the Eastern market.

While there is no general buying movement in finished steel product, a good tonnage is being booked from week to week, the aggregate falling only a little short of current production, and with the large volume of business on books in most lines it would take a long time for orders to run out, while progress into the spring is expected to take up the slack very soon.

Regular prices, f.o.b. Pittsburgh, are as follows:

Standard steel rails, $28 for Bessemer; $30 for open-hearth, f.o.b. mill, except Colorado.

Plates, $1.55 for tank quality, ¼ in. and heavier.

Shapes, $1.55 for I-beams and channels, 15 in. and under, zees and angles, 2 x 3 and larger.

Steel bars, $1.45 to $1.50, base.

Iron bars, $1.65 to $1.70, Pittsburgh; $1.55 to $1.60, Philadelphia; $1.50 to $1.55, Chicago; $1.40 to $1.45, St. Louis.

Wire nails, $1.85, base; plain wire, $1.65; galvanized barb wire, $2.15.

Black sheets, 28-gage, $2.40; galvanized, $3.50; blue annealed, 10-gage, $1.75 to $1.00; painted corrugated roofing, $1.70 per square; galvanized, $3.

Tin plates, $3.60 for 100-lb. cokes.

American Institute of Electrical Engineers.

At Charlotte, N. C., March 30-31 and April 1, will be held a meeting of the American Institute of Electrical Engineers.

Seven papers will be presented at this meeting as follows: "Electric Drive in Textile Mills," by Mr. Albert Milmow; "Gas Engines in City Railway and Light Service," by Mr. E. D. Latta, Jr., Charlotte Electric Railway, Light & Power Company; "The proportioning of Electrodes for Electric Furnaces," by Mr. Carl Hering, of Philadelphia; "Modifications of Hering's Law of Furnace Electrodes," by Dr. A. E. Kennelly, of Harvard University; "Some Demonstrations of Lightning Phenomena," by Prof. E. E. F. Creighton, of Schenectady; "Economics of Hydroelectric Plants," by Mr. W. S. Lee, chief engineer, Southern Power Company; "Method of Protecting Insulators from Lightning and Power Effects," by Mr. L. C. Nicholson, electrical engineer, Niagara, Lockport & Ontario Power Company, Buffalo, N. Y.

A special train de luxe for visitors from the North will be provided by the Pennsylvania Railroad should at least 100 passengers be assured. Applications for reservations should be made in advance to the A. I. E. E. headquarters, 29 West Thirty-ninth Street, New York, in order that the railroad may know if the condition as to number of passengers will be complied with. The train will be made up of parlor, smoking car, observation car, and the most modern sleepers and compartment cars available, and will be electrically lighted throughout.

As the climate of Charlotte is particularly delightful during the season when the meeting will be held, a large attendance is anticipated, which may reach 500 members and guests. Such a meeting is a novelty in the South, and the prominent men of Charlotte and surrounding towns are particularly interested in making it a great success. The committee on entertainment are much pleased with the lively interest taken by the ladies of Charlotte in the social program, and it is anticipated that the reception and dance in the Auditorium on Thursday evening, March 31, will be a particularly agreeable affair. Another feature that doubtless will be much appreciated by visitors is the trip arranged for the delegates, their wives and friends on Friday, April 1, by special train, to the two great generating plants at Great Falls and Rocky Creek, a detail of which is a Southern barbecue near the site of the former. On Wednesday afternoon there will be a visit to some of the electrically operated cotton mills near Charlotte, and on Thursday afternoon a reception to the visiting ladies will be given by Mrs. Stuart W. Cramer at her residence.

CORRESPONDENCE

Efficiency of Drying Machines.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—The exact use of words, always a desideratum, is especially necessary in scientific and technical literature and writers on technical matters cannot be too careful in choice of words, precisely to express what is meant.

As far as I am aware, the word "efficiency" as applied to machines in the accepted technical use, always means the ratio of actual useful effect to the theoretical or ideally perfect effect.

The "efficiency" of a machine is expressed by a fraction, the numerator being the attained result and the denominator the theoretical possibility, or

$$\text{Efficiency} = \frac{\text{Actual result}}{\text{Theoretical possibility}}$$

Of course, if expressed as a percentage, it will be 100 times this fraction.

Now the denominator of the above fraction, the theoretically possible result, is never practically attainable with any machine.

If we consider, for instance, the efficiency of an engine, 100 per cent efficiency would mean the ideal theoretical result of an engine working between two given temperatures, T_1 and T_2, and any losses whatsoever in a practical machine would reduce the efficiency, notwithstanding that some, at any rate, of such losses are quite inseparable from the operation of any practical machine.

Similarly with a boiler, "100 per cent efficiency" would mean the complete utilization of the heating power of the fuel in evaporation.

The fact that the waste gases must necessarily be discharged at a temperature higher than that of the steam generated makes it impossible that any practical boiler can reach 100 per cent efficiency. The loss is an entirely necessary one, but nevertheless it equally detracts from the "efficiency" of the boiler.

In an article on the "Efficiency Test of a Direct-Heat Dryer," in your March issue (page 162), efficiency is used in an entirely different sense and one, I believe, quite unwarranted by ordinary scientific usage.

To evaporate a given weight of water from any given temperature requires a definite amount of heat, let us say *a* b.t.u. A certain quantity of fuel will furnish a definite number of heat units, let us say *b* b.t.u.

A drying machine receiving *b* b.t.u. from the fuel burned and utilizing *a* units in *actual useful evaporation* has an "efficiency" equal to the ratio of *a* to *b*.

Now there are certain necessary losses in any drying machine which are well enumerated in the article in question. All of these losses reduce the numerator of the above fraction, and, in any consideration of "efficiency," all of them must be charged against the machine.

Among these losses is that due to heating up the material to the temperature at which it is discharged from the machine. This particular source of loss does not differ from any of the other sources of loss. It is, indeed, a variable, dependent upon the type of machine and upon the material to be dried. Its magnitude will vary with different materials. Nevertheless, in considering the efficiency of a dryer in any given case, the loss due to this cause must be charged against the machine, precisely as must loss from any other cause.

The writer of the article under discussion, however, *credits* the dryer with the heat diverted from useful work in this manner. In other words, he adds the heat required to heat the material to the discharge temperature to the heat required for actual evaporation, and calls the sum of the two "the theoretical heat required."

The ratio between this so-called "theoretical heat required" and that actually expended in useful evaporation he calls the "efficiency."

This is an entirely incorrect use of terms. The true efficiency of the dryer in the case cited is the ratio of heat received to heat utilized in useful work, or (taking the figures in b.t.u. from the article referred to) [illegible], or in round numbers, 54.5 per cent "efficiency."

There is no reason why this particular form of loss should be credited to the dryer any more than any other form of loss. It is indeed an unavoidable loss, but its magnitude is largely dependent upon the type of dryer. In the case discussed, the material was discharged at a very high temperature (224° Fahr.) and consequently the loss was high, notwithstanding the low specific heat of the material.

Had the machine been of a type that discharged its product at a lower temperature, the loss from this source would have been less and the "efficiency" greater.

It is perhaps proper to add that the "efficiency" of a drying machine is a relative matter and depends on the material to be dried.

The efficiency of a drying machine can only be stated for any particular case and may vary widely with different materials.

In the case in point, the material handled (sand) contained only 5 per cent moisture to begin with. Therefore, the weight of dried material discharged was very great relatively to the evaporation, and this condition is not favorable to the realiza-

tion of a high efficiency, particularly in a counter-current machine delivering its product at a high temperature.

The foregoing is not a discussion of any type of dryer, but of a proper use of terms. The performance of the dryer in the test was fair, but in no way remarkable. It evaporated, according to the figures given, 5.62 lb. of water per pound of (very bad) coal fired, or 6.25 lb. water per pound of dry coal. This is probably well up to the average performance of dryers and a good deal nearer the truth than the absurd evaporation figures frequently claimed. Only last month we were favored with an account in your columns of a dryer evaporating 16 lb. of water per pound of combustibles (page 108 of February issue). Such figures are immune from criticism by their very absurdity.

While the figures given in regard to efficiency test under discussion are fairly consistent, they lead to some remarkable conclusions.

The discharge temperature of waste gases is given as 100° Fahr. and the weight of air discharged as 31,905 lb. per hour. This air has to carry off 2250 lb. of water, or each pound of air must carry 0.0705 lb. of water. To do this it would have to be supersaturated to the extent of about 57 per cent; that is, the discharged air would not only require to be completely saturated with vapor, but must carry an additional burden of water in the form of mist (not vapor) equal to 57 per cent of its saturation water. To put it otherwise, something less than two-thirds of the water discharged was actually "evaporated," the rest being discharged, not as vapor, but as liquid water (mist). Of course, it does not matter in what form the water is got rid of as far as the efficiency of the dryer is concerned. Indeed, if it is possible to discharge one-third of the water as liquid water, it opens up a way to extraordinary possibilities in drying economies. Ordinarily, however, it is sufficiently difficult to attain complete saturation, let alone supersaturation.

Bayonne, N. J. W. E. Wadman.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The above criticism by Mr. Wadman of the dryer test, published in your March issue, was forestalled by paragraph three under heading "Heat in Dried Material." There it was stated: "It is, of course, a matter of definition how much of the heat which is carried off by the dried material should be considered as a loss," and as I stated my position in the matter there could be no possible deception and the discussion resolves itself into an academic discussion of terms which is unprofitable.

I still contend that my method of computation is a fair one. There is a decided difference between the loss in heating the drying material and the other losses enumerated. To attempt to dry sand, rock or most other inorganic materials at a low temperature by absorption would be absurd on account of the small capacity such a process could give. I therefore assume it is *necessary* to heat such material to 212°, just as necessary, in fact, as to heat and evaporate the water contained, so the dryer should be credited in doing this work. It is not necessary to heat the material above 212° (except in special cases); it is not necessary to carry off inconsumed carbon nor to have an excessive temperature of the exhaust air, not of the shell; therefore, such losses should be charged to the dryer.

Regarding the condition of the water and air of the exhaust, the air is probably fully saturated and is accompanied by a considerable quantity of watery vapor which can be as plainly seen as the exhaust from a steam engine. With the type of dryer from which the test in your March issue was made, it is often the case in drying clay or other very wet materials to evaporate 4500 lb. of water per hour with not over 6000 cu. ft. of air per minute passing through the machine. This means there is 88 grains of water carried off for each cubic foot of air, while the air if completely saturated would not hold over 21 grains per cubic foot.

New York City. W. B. Ruggles.

Energy Losses in Electrodes.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In the article by the writer on "Current Densities and Energy Losses in Electrodes," published on page 26 of your January issue, there occur some misprints, which should be corrected as follows:

Page 29, second column, second paragragh, line six, stands: "in the case," read: is the case.

Page 30, first column, first paragragh, line three, stands: "in the case," read: is the case.

Page 30, second column, fourth paragraph, line two, stands: (14), read: (15).

Page 31, first column, third paragraph, line eight, stands: $C_1\sqrt{1/a}$, read: $C_1\sqrt{1/a}$.

Page 31, second column, fourth paragraph, line nine, stands: agreement, read: square root.

Page 32, first column, sixth paragraph, line nine, stands: 1.07 volt, read: 0.07 volt.

Page 32, second column, sixth paragraph, line five, stands: extreme, read: electric.

Page 33, first column, sixth paragraph, line six, stands: correction factor, read: correction factor $\sqrt{1/2\,(1-c)}$.

Page 33, first column, eighth paragraph, line five, stands: $\sqrt{\frac{1}{2}\,(1-c)}$, read: $\sqrt{1/2\,(1-c)}$.

With reference to the editorial remarks in the same issue regarding this article the writer wants to point out, in order to avoid misconceptions, that his introduction of a coefficient c, appearing as a factor to the Joulean heat loss, ought not to be interpreted as a lumping together of the heat leakage into the surrounding medium with half the Joulean heat loss, but as an expression for the fact that this heat leakage will reduce the efficiency of the "check-valve action" of the Joulean heat upon the heat conduction from the charge. Using the language of the editorial, where H is the heat which would flow if there was no current, the electrode loss is expressed in the following way, when there is heat leakage into the wall: $[H-(1-c)\,i^2r] + i^2r$ as against the theoretical case when no such leakage occurs: $[H-\frac{1}{2}\,i^2r] + i^2r$.

Höganäs, Sweden. Jakob Forssell.

Silundum.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—From the letter of Dr. E. G. Acheson in your issue of February I learn that he did not express himself, as reported, at the meeting of the American Electrochemical Society. I see, however, in your number of January that you refer, page 64, to silundum as having the same chemical compositions as siloxicon.

Dr. Acheson states that "in analyzing the possible reactions and the products that may be obtained from these three elements (carbon, silicon, and oxygen) we find that the furnace content may be so proportioned and the furnace so operated as to produce either graphite, metallical silicon, carborundum or amorphous carbide of silicon, or we may have all the three elements so associated as to produce siloxicon. As to the possibility of any other product being made, I am not advised, but the foregoing were old before the world was informed of Mr. Bölling's experiments."

I stated in my original article: "A process was worked out and patented by which it is possible to convert any piece of carbon, in form of tubes, round or square, rods, bricks, crucibles, pieces of coke, charcoal into *silicon carbide*. Silicon carbide was known so far only in the amorphous and crystalline state, and it was supposed that it was formed by the sublimation of silicon and carbon at high temperatures." Silundum, as the new material has been named, or silicified carbon, is, therefore, a product that is obtained when carbon is heated in a vapor of silicon "and, farther on, silundum is another form of silicon carbide."

I am of the opinion that my original article on silundum states clearly that it is a silicon carbide, and I do not see any reason why a discussion should take place on the chemical composition of silundum. If Dr. Acheson reads my original paper he will find that silundum falls under the products named in his letter. I do not claim to have discovered a *new chemical compound*. What I claim is the discovery of a new process to convert any piece of carbon into silicon carbide or covering it with silicon carbide preserving its original shape.

Silundum contains silicon in various percentages. Pieces are found that look like carbon, but are incombustible, others in a farther state of conversion have the appearance of siloxicon and amorphous silicon carbide. The next state is a material that has a metallic appearance; it contains the largest amount of silicon. If pieces of any of these modifications are heated to a higher degree, silundum crystallizes and is converted into carborundum.

Silundum may be converted into graphite in modifying the charge. There seems to be some probability that under certain conditions the black diamond may be obtained from silundum by depriving it of its silicon.

I may say that the hardest modification of silundum is used in some places for boring purposes, replacing the diamond.

Oberwesel, Germany. F. Bölling.

The Trust from the Standpoint of an Engineer.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In the March issue of this magazine there appeared an interesting discussion of "The Trust from the Standpoint of an Engineer," by Mr. W. McA. Johnson, evidently inspired by reading the brief for the defense in the action against the American Tobacco Company, brought under the so-called "Sherman Anti-Trust Law." In view of certain statements which appeared in Mr. Johnson's letter, a further short discussion may be of general interest, especially as regards the Supreme Court of the United States.

The fact that the Federal Anti-Trust Act passed in 1890 has remained on the statute books unamended for 20 years tends to show that it was not the product of a discontented minority, but was and is the crystallization of public opinion into law, a law that is worthy of a conclusive test both as to legality and practicability. When the Supreme Court decides a case under this statute, the duty of the justices is simply to construe the law and apply it to the concrete case presented, leaving to the law-making body the responsibility as to the statute's expediency. Now the members of the court will bring to the decision of the Tobacco Company case both ripened expert knowledge of law and an impartial habit of mind, and, furthermore, they will examine *all* the facts in the light of arguments presented by the prosecution, as well as by the defense.

If the Court decides that the facts proven make the Tobacco Company guilty of a misdemeanor as defined in the law made by Congress, Mr. Johnson implies that it will forfeit a large share of his respect. A man who is not an expert in law and who has read simply the argument for the defense (made by a lawyer hired solely because of his ability to present one side of the question) is hardly in a position to criticize a decision reached by the highest of our courts after an impartial and complete examination of all the evidence.

The statement that the "trusts" are necessarily the survival of the fittest and are therefore assured of longevity depends on the meaning attached to the word fit. The simple plan that "they should take who have the power and they should keep who can" has undergone extensive revision in the ascent from barbarism to civilization, so that society to-day compels the takers and keepers to confine their operations within the bounds of necessary laws, which are as real a product of an evolutionary process as anything else.

Mr. Johnson considers one great corporation "fit" because it is approved by public opinion and evidence of this general approval he finds in the fact that the people have not demolished it. The conclusiveness of this reasoning is open to serious question. It is a safe opinion that the majority of American citizens would not resort to physical violence until wrongs far greater than any ever charged against the Standard Oil Company have been proven to them, and then not until the Government, which is established for preserving order and justice, is shown to be unable to cope with the situation. Rather will the average man wait to see the status of the giant monopoly established by the judicial machinery created for that purpose, namely, the Supreme Court of the United States. The legal status being determined (one factor in the judgment of its "fitness") its survival as an economic power will be decided by its future life and prosperity.

If manipulation of prices or other facts show that the trust is guilty of a misdemeanor as defined in the "Sherman Act," and Mr. Johnson thinks those facts should not constitute a misdemeanor, his objections should be aimed not at the Court, but at the law-making body and at the dormant public opinion which permits the law to remain unamended.

Mr. Johnson's dismissal of rebates as special favors to friends and as similar to a discount given to a grocer who promises to handle a single brand of goods, seems inaccurate, for the analogy is superficial. A grocer's business is private, while the railroads are "common-carriers," a class of beings who, even before the steam locomotive was dreamed of, were considered to be under very special obligations to the public. The railroads are the highways of the nation, deriving their rights, the land on which they are built, and their corporate existence from the State. The prevailing idea is that in giving up these highways of commerce to be developed by private enterprise, the State should insist that all its citizens be treated on an equal basis. Instead of being a matter of friendship between carrier and shipper the transaction was often in the nature of a hold-up. The evils of rebating are matters of business history; and public opinion, forcibly expressing itself in the Interstate Commerce Act, has rightly banished the practice.

The "trusts" which control the selling prices of commodities seem in certain industries to be the most efficient form of organization now known and are (as Mr. Johnson states) the result of a process of evolution following definite economic laws. But there exist no economic laws compelling corporation managers to be scrupulous in controlling prices. A few of them at least have not been so. There is nothing in any evolutionary theory that precludes adequate protection of the public welfare; indeed, the general welfare demands that these leaders be subject to the reasonable restraints of the law. It is the opinion of the majority of competent judges that the English common law, which was gray-headed before the beginning of our industrial era and was chiefly developed in a state of society widely different from our own, is inadequate unless revised and amplified. The necessity for such modification is at once a reason and justification for legislation by Congress. This will tend toward an equitable division of the profits resulting from the corporate form of organization among the three parties of interest, namely, the corporation itself, its employees, and the consuming public.

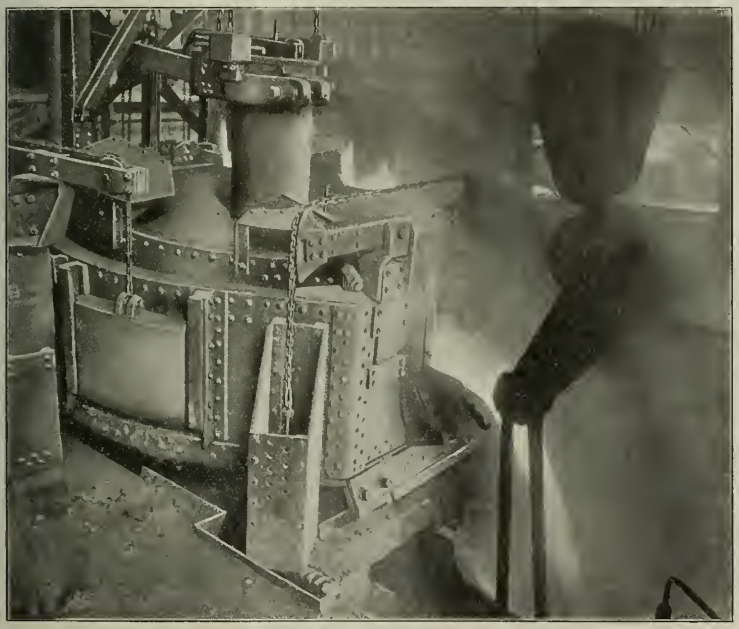
Beginning a little over a century ago with the perfecting of the steam engine and the resultant displacement of hand processes by power-operated machinery, there has come a wonderful creation and development of industries, accompanied by a corresponding revolutionary change in the employment and living conditions of civilized peoples. Also accompanying this evolution there has been a progressive development in the organization of industry, culminating in the "trusts" created within our own time. The institutions and practices which this century of change has produced have existed but a brief interval, historically speaking; they are now on trial, and will be altered or discarded as experience teaches.

Washington, D. C. Ray L. Stinchfield.

The South Chicago Electric Furnace Plant of the United States Steel Corporation.

When in February of last year the United States Steel Corporation adopted the Héroult electric furnace for steel refining, it was decided to erect, as a beginning, two Héroult furnaces, each of 15 tons capacity, one at the South Chicago works of the Illinois Steel Company and the other at the Washburn & Moen plant of the American Steel & Wire Company, at Worcester, Mass. At South Chicago the electric furnace is used for refining molten metal from the Bessemer converter, at Worcester for refining molten metal from the basic open hearth. The object of the combination of the ordinary acid-lined Bessemer converter and the electric furnace (South Chicago) is to produce steel of open-hearth steel quality or better at less cost. The object of the combination of basic open-hearth and electric furnace (Worcester) is to produce steel better than the best acid open-hearth steel in quality, at a slightly advanced cost.

The undertaking of the United States Steel Corporation involved some interesting and important novel points. The largest



HEROULT ELECTRIC STEEL FURNACE AT SOUTH CHICAGO.

Héroult furnaces installed before that time had a capacity of five tons. In the Héroult furnaces of the Steel Corporation this capacity was trebled. Further, the Héroult electric furnace had been used before on a commercial scale with cold charges, and with molten metal from the open-hearth furnace (as in the pioneer American Héroult plant of the Halcomb Steel Company in Syracuse); but in South Chicago it was to be adopted for the first time in America on a large scale in combination with the Bessemer converter. Finally, while in the past the Héroult process had been used essentially as a substitute for the crucible steel process for the manufacture of high-grade tool steels, etc., it entered into a much wider field of usefulness at South Chicago and Worcester, where it is used for large-tonnage products (tonnage steel), like rails, axles and wire.

The South Chicago plant has been in continuous operation since May of last year, while the Worcester plant was started in the beginning of this year. The South Chicago plant is perhaps the more interesting of the two, since it includes the more involved metallurgical process of both dephosphorization and desulphurization of the steel in the electric furnace, while the metal charged from the basic open-hearth into the electric furnace at Worcester is already largely dephosphorized.

Further, the combination of the electric furnace with the Bessemer converter seems a matter of momentous commercial importance. For a number of years the cry of the consumer has been for better steel for many purposes, like rails, etc. As a result, there has been a decided tendency away from the converter and toward the open hearth. Many have prophesied that it would be necessary to use open-hearth steel almost exclusively in future and that the Bessemer converter plants were doomed. If the electric furnace in combination with the Bessemer converter can make as good or better steel at the same or less cost than the open hearth alone, it means that the electric furnace gives a new lease of life to the converter. Far from being a competitor to the old methods of steel metallurgy, the electric furnace becomes the savior of the converter plants and prevents their being scrapped. From this viewpoint the results obtained with electric refining at South Chicago are of broad commercial significance and importance.

By a special invitation extended to us by Dr. Paul Héroult we were enabled to inspect, on March 12, the electric furnace plant of the Illinois Steel Company at South Chicago. The inspection extended almost over the whole day; we were given every possible facility of inspection, while information on all questions asked was given without reserve. Our thanks are due to Dr. Héroult, to Mr. W. A. Field, general superintendent of the Illinois Steel Company, and to the many officials and employees of the Illinois Steel Company who gave us information.

The most important question that will be asked is, of course, whether the Héroult furnace in combination with the Bessemer converter is now beyond the experimental stage. This question must be answered unreservedly in the affirmative. There is nothing experimental whatever about the operation of the Héroult furnace in South Chicago. There is no "fussing" about the furnace. No nervousness is displayed as to whether something might go wrong. The whole operation is carried on with such self-evident certainty and assurance as comes only from firmly established routine.

That the Héroult furnace at South Chicago is a commercial metallurgical apparatus and no longer in the experimental stage is also proved by the regularity with which the heats follow each other. The furnace is in continuous operation during the whole week, and operation is discontinued only on Sunday, the converter plant not working that day. When the converter plant closes down in the night from Saturday to Sunday, the metal from the last converter blow is transferred to the electric furnace and refined; then the electric furnace plant closes down till Monday, when the first metal blown in the converter plant is transferred to the electric furnace.

As an indication of the regularity of operation we give in

Table I the net weight of metal charged, the kw-hours consumed, and the durations of 11 successive heats made on March 10.

TABLE I.

Net weight charged. Lb.	Kw-hours used.	Time.
29,000	2000	1 hour 20 minutes.
28,200	2300	1 " 35 "
28,200	2500	2 " 15 "
28,000	2200	1 " 30 "
26,600	2100	1 " 15 "
26,000	2200	1 " 40 "
25,700	2900	2 " — "
23,000	2500	1 " 35 "
28,000	2400	1 " 35 "
27,000	2300	1 " 35 "
27,400	2700	1 " 45 "

On the average 12 heats are made a day. The figures given under time are the time in hours for which the current was on during each heat. It will be seen that during the 24 hours of this day the current was on for 18 hours and 5 minutes, so that the intervals between the successive heats (during which no electrical energy was consumed) amounted to 5 hours and 55 minutes, or 33 per cent of the whole time.

The average specific energy consumption of the 11 heats of Table I is 88.4 kw-hours per 1000 lb. net weight, or 194.5 kw-hours per net metric ton. In this case the electric furnace treatment, it should be remembered, involved both desulphurization and dephosphorization.

If the charge supplied to the electric furnace is already low in phosphorus, the specific energy consumption is, of course, less. As an example we give in Table II the figures for 9 successive heats made in 12 hours on Jan. 28.

TABLE II.

Net weight Lb.	Kw-hours.	Kw-hours per metric ton.
28,000	1400	110.0
27,600	1700	135.5
27,000	1400	114.1
28,000	1000	78.5
28,000	1300	102.1
28,400	1300	100.8
27,800	1000	79.2
27,600	1500	119.5
28,100	1200	93.9

The average specific energy consumption of the nine heats of Table II is 47.2 kw-hours per 1000 lb. net weight, or 103.8 kw-hours per net metric ton.

As to the electric power supply, it should be stated that the electrical energy is generated by means of gas engines operated with blast furnace gas and that the two plants of the Steel Corporation at South Chicago, Ill., and Gary, Ind., are electrically connected in parallel. The power generation is highly economical. The charge for energy supply, made to the electric furnace plant, is ½ cent per kw-hour actually consumed, as taken from the meters.

As to the reliability with which the desired composition of steel is produced, we give here the specification and analyses of eight successive heats made during part of March 11. In all these cases axle steel was made.

The first line, marked "Specification," gives the desired specified composition of the steel, while the next lines, marked "Analysis," give the analyses of the steel produced in these eight heats.

TABLE III.

		C	S	P	Mn
Specification	Axle steel	0.35 to 0.45	0.03	0.03	0.37
Analysis	[illegible] lbs	45	0.032	0.03[illegible]	0.49
	[illegible],000 "	.37	.028	.033	.42
	[illegible],000 "	38	.028	.026	.39
	[illegible],000 "	.35	.031	.037	.38
	[illegible] "	.41	.030	0.39	.47
	[illegible] "	.48	.025	.032	.41
	[illegible],000 "	.42	.030	.027	.44
	[illegible] "	35	030	.028	.31

It should be said that the above data were not selected by the writer for any particular purpose, but were taken at random from the regular works records.

The regularity of operation which makes the Héroult furnace at South Chicago a thoroughly commercial apparatus is due in no small degree to the simplicity and compactness of construction of the Héroult furnace and the total absence of any complications whatsoever, either electrical or otherwise, with the possible single exception of the electrodes at the top, which will be particularly discussed.

The furnace as used in South Chicago is shown in the adjoining illustrations, Figs. 1 and 2, for which we are indebted to Mr. R. H. Wolff, Dr. Héroult's representative in this country. The Héroult furnace has been so often described in this journal that there is no necessity for any further details at this place. To characterize the design briefly, it is essentially built like the body of an open-hearth furnace, the heat being supplied from the electrodes through the top. There are three electrodes in the South Chicago furnace, since it is operated by three-phase currents.

The simplicity of the construction results in great convenience of repairs of the furnace proper. During the whole period of operation at South Chicago, from May, 1909, until the present, it is stated that there has never been any necessity to stop the Héroult furnace for the sake of repairs.

The lining is kept in good condition by throwing some shovels of broken burnt dolomite into the furnace upon the corroded portions of the hearth. This is done between successive heats and requires not more than a few minutes; no extra help is required. The consumption of dolomite for repairs is given as 10 lb. of dolomite per ton of steel.

The silica roof has been generally repaired or replaced during the regular stop on Sundays. The last roof, however, lasted 129 heats. The replacement of the roof is a very simple matter, a new roof being always kept in reserve.

The banks (side walls) of the present furnace have stood since Nov. 16, 1909, and there is not yet any necessity for reconstructing them.

The cost of repairs is, therefore, very low. It is given as follows: A silica roof costs $60; if it lasts for 129 heats the cost of the roof per ton treated is about 3 cents. The 10 lb. of dolomite ($6 per ton) required for repairing of the lining per ton of steel cost also about 3 cents. Hence, the total cost of repairs of the furnace proper is approximately 6 cents per ton, which is a remarkably low figure.

As to the electrodes, their consumption is given as averaging 6 lb. per ton of steel, and this figure is stated to be true both for graphite and for amorphous carbon. It is the item of the cost of electrodes which, it is expected, can be very materially reduced in future.

The original intention was to use amorphous carbon electrodes. But it was found very difficult to make very large homogeneous carbon electrodes. While with smaller furnaces amorphous carbon electrodes are in satisfactory successful use, the manufacture of such electrodes for the large 15-ton furnace has met with difficulties in baking and it appears that the problems involved have not yet been solved.

In the beginning of operations, when baked amorphous carbon electrodes were used at South Chicago, they frequently cracked at a most inopportune moment, and caused great trouble. Since the quality or strength of the carbon electrodes obtainable did not materially improve, it was necessary to have then recourse to the more expensive graphite electrodes. These have been and are now doing the service very satisfactorily and no such electrode troubles are now experienced. The intention is to try to solve the problems involved in the baking of large durable homogeneous amorphous carbon electrodes, as their use would reduce the cost of the electric refining process considerably. In every respect except higher first cost the graphite electrodes are exceedingly satisfactory.

The electrodes as used at present are made up of Acheson graphite rods, 48 in. long and 8 in. in diameter. Three such rods are butt-connected to a total length of 144 in., and three

such 144-in. rods are arranged side by side to form a single electrode, consisting thus of a solid bundle of three rods, each 144 in. long, and with cross-section a true shamrock. We might say each electrode is made up of three rods in parallel, each rod consisting of three 48-in. rods in series. A water-cooled jacket is provided around each electrode, just above the openings in the roof.

We now give the record of the operation during one complete heat. The temperatures given in this record were measured with a Mesuré-Nouel optical pyrometer by Dr. Jos. W. Richards, who accompanied the editor of this journal in the inspection of the plant

11 a. m.—Finished steel poured from electric furnace into ladle (temperature 1495° C.) and then from the ladle into ingot. The two side doors of the electric furnace are open. Dolomite shoveled into electric furnace to repair lining.

11.10 a. m.—Mill scale charged for next heat.

11:16 a. m.—Charging launder put in place in mouth of electric furnace.

11:18 a. m.—The new charge of Bessemer metal (30 to 40 seconds overblown) arrives in ladle and slag is poured off. Temperature of empty electric furnace 1300° C.

11:21 a. m.—Pouring of Bessemer steel from ladle into the electric furnace. Temperature of Bessemer metal while being poured into electric furnace, 1500° C.

11:24 a. m.—All Bessemer metal poured into electric furnace. Temperature of empty Bessemer ladle, 1500° C. Electric circuit closed. The electrodes are first regulated by hand, later by automatic electromagnetic regulation (Cuenod).

11:28 a. m.—Charging launder removed. Yellow flames seen, probably from the oil and grease in the mill scale.

11:40 to 11:45 a. m.—One hundred and twenty kw-hours consumed in five minutes. Power-factor, 90 per cent.

11:50 a. m.—Twelve shovels of mill scale added.

12 m.—Temperature inside furnace, 1425° C. Temperature of hottest electrode just outside the furnace, 1050° C.

11:45 a. m. to 12 m.—Three hundred and eighty kw-hours consumed in 15 minutes. Power-factor between 82 per cent and 86 per cent.

12:28 p. m. to 12:33 p. m.—About half the slag skimmed from the bath. Temperature of slag, 1400° C.

12:35 p. m.—Added manganese ore.

12:37 p. m.—Added lime.

12:45 p. m.—Half of the "phosphide slag mixture" charged (see patent of Humbert on page 48 of our January issue). This slag mixture had been previously made up of coke dust and fluorspar.

12:54 p. m.—Rest of "phosphide slag mixture" added.

12:58 p. m.—Ferromanganese and ferrosilicon added.

1:01 p. m.—First test sample taken.

1:08 p. m.—Test made shows that heat is ready for tapping.

1:11 to 1:13 p. m.—Furnace emptied. Temperature of empty furnace, 1500° C.; this temperature dropped 200° C. in 15 minutes, while doors were open to patch up the furnace and make ready for the next heat.

There are altogether four attendants at the furnace: one head melter, one assistant and two workmen. A helping hand is lent by other workmen around the works while tapping and pouring.

At the time of our visit, and during the preceding week, axle steel was made. Rail steel has also been made, also high-manganese steel, ordinary steel castings and manganese-steel castings.

Simply to try what can be done with the electric furnace, a very severe test was made some time ago in which, it might be said, the electric furnace was used as a scavenger. As Mr. Field, the general superintendent of the Illinois Steel Company, explained, they swept up the works to find the worst kind of scrap (plate scrap, rusty nails and everything that was found) and tried to make a fine heat out of it. The electric furnace proved equal to the task.

The specification was to produce steel

C, 0.35 to 0.45; S, 0.04; P, 0.04; Mn. 0.35 to 0.50.

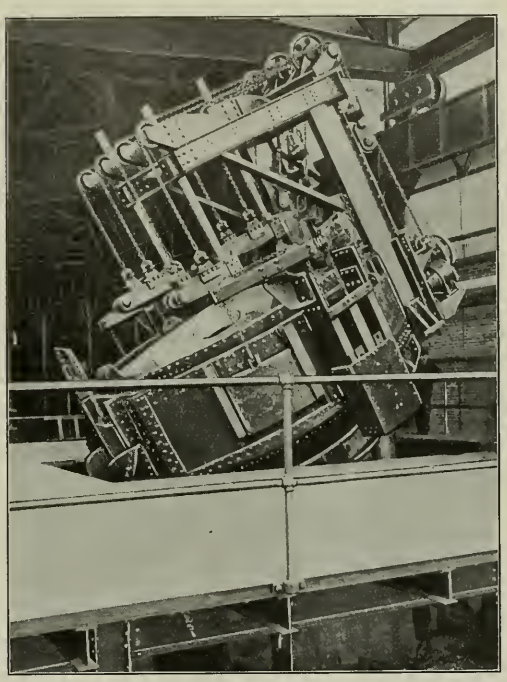
The steel produced analyzed:

C, 0.46; S, 0.037; P, 0.024; Mn, 0.34.

There were charged in this test 9000 lb. hot pig iron, 12,000 rail ends and 9000 stove-plate scrap, "the worst stuff to be found." The product was 31,800 lb. of steel.

The energy consumption during this remarkable test was 14,450 kw-hours. This test was simply made to see what could be achieved with the electric furnace, and proved that it has apparently no ordinary limitations to its refining capabilities.

As to the mechanical tests of the steel now being made by the



HÉROULT FURNACE DIPPED.

Héroult Bessemer-electric process at South Chicago, the following data were given at the mechanical testing plant of the Illinois Steel Company: Elastic limit, 35,000 to 47,000; tensile strength, 60,000 to 70,000; elongation, 25 per cent to 30 per cent; reduction of area, 43 per cent to 60 per cent. As to the difference between this electric steel and acid open-hearth steel it was stated that the same tensile strength is obtained with the electric steel with lower carbon than with open-hearth steel. For example, an 0.10 C electric steel averages the same tensile strength as an 0.15 C to 0.17 C acid open-hearth steel.

As to the general arrangement of the plant it may be said that there was not space available to erect the electric furnace in the immediate neighborhood of the Bessemer plant. The molten Bessemer metal has to be brought from the Bessemer plant to the electric furnace over a distance of a fourth of a mile. Of course, in a new works, built for the proper combination of converter and electric furnace, this would be arranged differently.

In conclusion, we congratulate Dr. Héroult and the United States Steel Corporation on the signal success achieved in their pioneer Bessemer converter-electric furnace combination plant.

which, we have no doubt, is the forerunner of many similar installations, and marks the beginning of a new commercial epoch in practical steel making in America.

The Decomposition of Carbon Monoxide in Presence of Catalytic Agents and in the Blast Furnace.*

By Fritz Zimmermann, Ph.D.

At the last meeting of the American Electrochemical Society in New York, Mr. Edward R. Taylor presented a very interesting paper on the electric smelting of iron ore. In the discussion following this paper, it was pointed out that an attempt should be made to construct electric furnaces in such a way that the escaping gases should consist of practically nothing but N and CO_2 and that, if this would be possible, the energy efficiency, of course, would be very much greater than if they contained a large percentage of CO.

Mr. Lidbury pointed out that there is a ratio between the CO and the CO_2 which is governed by the conditions prevailing—that is, the temperature and the nature of the substances present, which fixes a limit beyond which no further reduction will take place at the expense of the CO.

It might be of interest to give a short compilation of some studies and experiments that have been undertaken by others and myself to study some of the phenomena which are taking place in the blast furnace.

The production of iron in the blast furnace was, until almost the middle of the nineteenth century, purely empirical. Bunsen undertook the first steps to put it on a scientific basis in order to obtain the best possible results. His work on gas analysis enabled him to investigate the composition of the blast furnace gases in different parts of the blast furnace. He found that the carbon dioxide escaping from the furnace always contained more than the double amount of carbon monoxide, naturally causing a big loss of fuel. He was the first one to say that "we cannot really speak of utilizing our fuel properly until someone is able to construct a furnace from which only carbon dioxide will escape besides the nitrogen of the blown-in air."

Assuming that the large amount of carbon monoxide, which usually escapes from the ordinary low furnace, could be forced to reduce more iron ore, Lowthian Bell, the celebrated English metallurgist, began about 1860 to construct furnaces of a very great height. His reason for constructing these furnaces was that the carbon monoxide, instead of passing out into the air, as it always does in low furnaces, should meet more iron oxide, which it could reduce, so that all the carbon monoxide would be utilized. His experiments were a failure, and he was unable to explain why the proportion of CO to CO_2 remained the same as in the old low furnaces.

Le Chatelier, in his "Recherches Experimentales et Theoriques sur les Equilibres Chimiques" (1888), found an explanation. He came to the conclusion that an equilibrium is established between iron, iron oxide, CO and CO_2 which does not depend much upon the temperature. Gas, containing less CO than necessary for this equilibrium, is not able to act reducing on iron oxide; if more iron be present than corresponds to the equilibrium the reversibility of this process will show itself by partly oxidizing the iron until there is again equilibrium.

But the process of reduction is not the only one taking place in the blast furnace. Sometimes we observe a strong precipitation of finely divided carbon in a certain zone of the furnace. This may be so considerable as to clog up the furnace and stop the running of it. For a long time this precipitation of carbon could not be explained until something similar was found in the manufacture of steel.

In continuing certain work done by Berzelius and Saunderson, Caron found that, in passing CO over iron, finely divided carbon was precipitated. He thought it was silicon that caused this precipitation. In his work "Sur la Dissociation de l'Oxyde de Carbone," Saint Claire Deville used a very ingenious apparatus—his cold and warm tube. This consists of a porcelain tube, closed with two double perforated stoppers; through one set of holes a brass tube is placed, which serves for passing cold water through it; through the others, gas may pass. Heating this tube to a strong red heat, he passed pure CO through it, while cold water was flowing through the brass tube; under these conditions, CO was decomposed into CO_2 and carbon. He explains it as a partial decomposition of CO while hot into oxygen and carbon. He assumes that, at the moment the products of dissociation touch the cold tube, they are taken

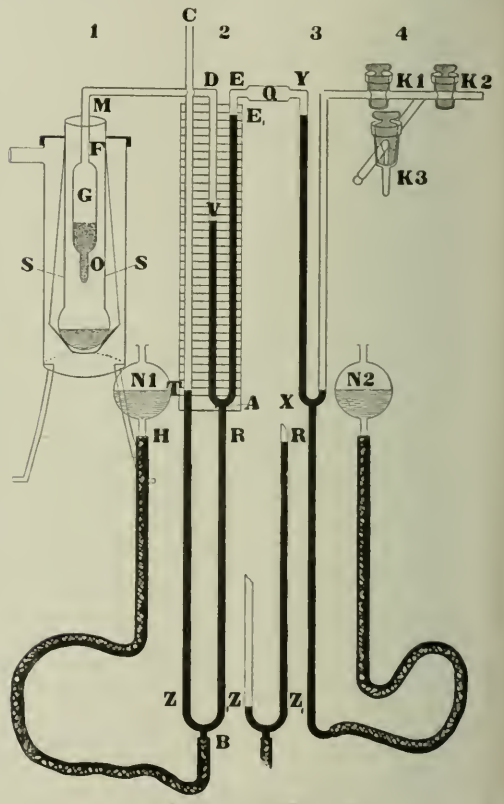


FIG. 1.—ARRANGEMENT OF TEST.

away from the influence of the heat, which otherwise would unite them again. Carbon is precipitated on the cold brass tube, and the free oxygen combines with free CO, forming CO_2.

Stammer got similar results by passing CO over iron oxide. He found that, while the oxide was reduced to metal, iron carbide was formed at the same time, and a precipitate of carbon took place upon the iron.

Gruner, and later Berthelot, worked on similar subjects—the first saying that only the presence of oxide caused a decomposition of CO and that pure iron could not decompose CO, while the latter assumed that a complicated polymerization took place.

Boudouard undertook a series of experiments to study the decomposition of CO in the presence of metallic oxides which, as he assumed, would act as catalytic agents. He used the oxides of nickel, cobalt and iron in the presence of CO in a sealed tube, and analyzed the products of reaction. He found that the speed of reaction and the equilibrium depended upon

*A paper read before the New York section of the American Electrochemical Society on March 16, 1910.

the temperature. At a temperature of about 445 deg. C., in the presence of the metal oxides as catalysers, decomposition should be complete according to the equation of $2\,CO = CO_2 + C$, while, by increasing the temperature, the reverse reaction $C + CO_2 = 2\,CO$ takes place more and more.

To get a better knowledge of these cross reactions, Professor Schenck, then in Marburg and now in Aachen, induced me to make a special study of the character of these reactions. The reaction $2\,CO = CO_2 + C$ is effected with a contraction in volume of 50 per cent, for we start with two molecules CO and come to only one molecule of CO_2, C being precipitated.

By constructing a proper apparatus, this contraction will allow us to follow the speed of reaction.

After building a great many apparatus, I finally came to the following construction, which seemed to answer my purpose in every respect. The apparatus consists of four main parts.

I.—*G* is a vessel of Jena glass of about 100 c.c. capacity, intended to be filled with a gas and whatever catalyser shall be used; from *F* on the right side of the apparatus it consists of capillary tubing, so that its capacity may be neglected compared with the 100 c.c. of the heating vessel.

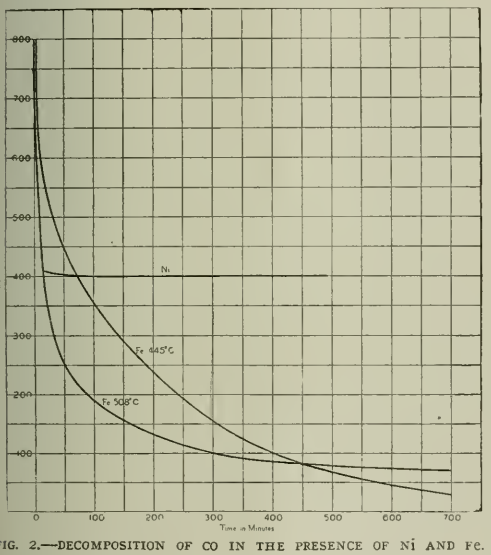

FIG. 2.—DECOMPOSITION OF CO IN THE PRESENCE OF Ni AND Fe.

Before being used *G* is cleaned well with sodium hydrate and afterwards with chromic and sulphuric acid. Then it is filled with a catalyser through the wide tube *O*, which afterwards is closed by melting it together in a gas flame; then the capillary tube is molten on the apparatus at the point *M*. In order to heat *G* uniformly, it is put in a little furnace consisting of a wide tube *S* of Jena glass standing on an iron bath, protected by asbestos and sheet iron. In *S*, different substances, like diphenylamin, mercury, sulphur or sulphide of phosphorus may be boiled.

II.—Consists of two barometers, one put on top of the other; the tube *AB* is 800 millimeters long, *AE* and *AD* are of the same length; *BC* is a little above 1600 mm; BH_1 is heavy rubber hose, around which heavy linen is sewed in order to prevent it from expanding by the weight of the mercury in the vessel N_1. If N_1 is lowered to Z, the mercury will stand equally high in both tubes *BA* and *BC*. By evacuating the apparatus, the mercury in *BA* will rise to *R* and the height of mercury Z_1R or the distance between *Z* and *R* being the atmospheric pressure. Of course, the mercury cannot rise higher than *R*. If gas is allowed to flow into the apparatus, it will fill *G* and the mercury in *AB* will fall according to the pressure of the gas. If it is less than an atmosphere, N_1 does not need to be changed from its position; if it is more than an atmosphere, N_1 must be lifted up. The distance between *R* and *Z* is plus or minus according to the pressure of the gas. After gas has passed into *G*, N_1 is lifted to *T*, sealing off the gas entirely. If we evacuate now, the mercury in the tube on the right *AE* will rise to *E;* the distance between E_1 and *T* being the atmospheric pressure. The distance between E_1 and *V* indicates the absolute pressure of the gas in *G;* so that the pressure in *G* can be measured either by the scale distance between E_1 and *V* or, what is the same, the distance between *T* plus atmospheric pressure and *V*.

Q is a vessel to collect drops of mercury that might fly out of *AE* or *XY*.

III is another double barometer, the only difference between it and II being that it has no connection with the outside air as *BC*.

IV.—K_1 and K_2 are ordinary gas cocks; K_3 is a three-way cock leading to vacuum pump, gas developer or gasometer or hood respectively.

In order to get the finely divided catalyser, pumice stone cut to the size of a pea was used. As acid alone did not remove all the iron oxide in the pumice stone, it was reduced first with hydrogen; after this, it was easy to remove all the iron and get an absolutely white product.

In the following experiment, cleaned pumice stone was impregnated with a solution of pure nitrate of nickel—2 grams of nickel to 20 grams of pumice stone being used; the solution was evaporated together with the pumice stone, and afterward the impregnated pumice stone was highly heated on a blast burner until the nitrate was decomposed and only nickel oxide remained. After the apparatus had been thoroughly cleaned and dried, the pumice stone impregnated with nickel oxide was placed in vessel *G*, which was then evacuated and heated by immersion in boiling sulphur. CO was then passed into the apparatus and the vessel N_1 raised to *T*. No contraction could be seen.

It might have been that the reaction and contraction had been completed in the first 30 or 40 seconds which were required to flow in the gas and raise the mercury vessel, so that this contraction could not be seen. In order to be sure whether this was the case or not, the apparatus was filled, while cold, with CO, heated to 445 deg. C. and let cool again. The volume was equal to its original. The same result was obtained in heating to 320 deg. C., 360 deg. C. and 508 deg. C. The analysis of the gas contents showed CO_2 only. This proves that the reaction taking place is only a reducing reaction $CO + NiO = CO_2 + Ni$, which, of course, does not show any contraction.

I also observed no contraction after using cobalt oxide or iron oxide. The only reaction taking place in each case was a partial reduction of the metallic oxide. This proves that the oxides of nickel, cobalt and iron are no catalytic agents able to bring about the decomposition of CO to $CO_2 + C$, as had been claimed.

In the next experiments, pure metals were used instead of the metallic oxides; the metals being obtained in a finely divided state by reducing the metallic oxides precipitated on the pumice stone. Nickel was used first; after using every possible precaution, CO was allowed to pass into the vessel at 445 deg. C. Reaction took place immediately, causing strong contraction, which came to a standstill after heating for about an hour. A contraction of 80 per cent of the pressure, observed in the beginning, had taken place.

The experiment was repeated several times, practically with the same result.

At 360 deg C. contraction, which could be measured, was slower than at 445 deg. C. and amounted to 91 per cent.

At 310 deg. C. the temperature of boiling diphenylamin, the reaction was slower and came to standstill after seven hours; the decomposition being 96%. Cobalt gave similar results.

In order to see whether the equation $2CO = CO_2 + C$ and with it a contraction of 50 per cent takes place, cobalt as catalyser was used. The vessel was filled, while cold, with CO, then heated and afterward allowed to cool in cold water to the same temperature as before. The contraction was exactly 50 per cent, showing that CO really had been decomposed into $CO_2 + C$. The gas analysis showed practically nothing but CO_2.

With nickel, the same experiment could not be made, on account of nickel tetracarbonyl being formed. In order to see whether the presence of CO_2 would change the reaction, a mixture of CO and CO_2 was passed into the apparatus. The contraction was 50 per cent of the CO contents, so that the CO_2 did not seem to have any influence on the reaction.

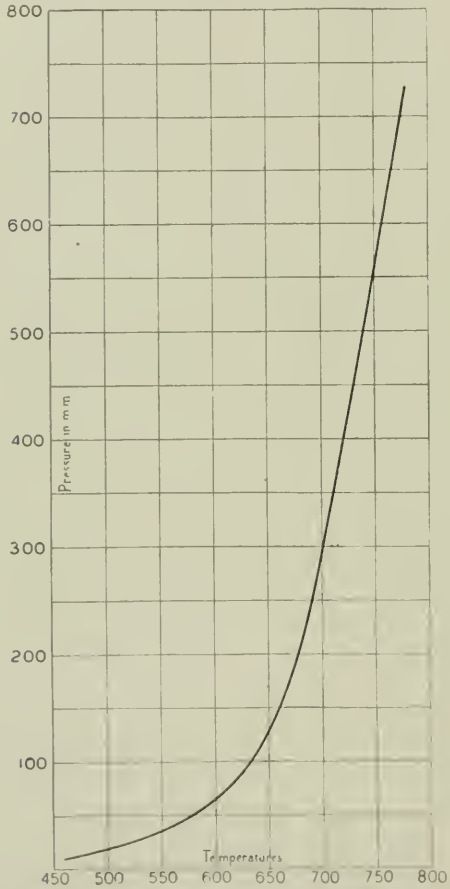

FIG. 3. PRESSURE CURVE CO + CO_2 AT DIFFERENT TEMP. IN THE PRESENCE OF Fe ACCORDING TO SCHENCK.

In the following experiments, iron as a catalyser was used. At 360 deg. C. the reaction was very similar to that of nickel and cobalt, but at 445 deg. C. a very curious phenomenon took place. The decomposition did not only go to 50 per cent, but the contraction continued and came almost to a vacuum. For instance, starting with 787 mm pressure, after heating nine hours, we came to 32 mm. In another series of experiments at 508 deg. C., very rapid contraction took place, but the final pressure was a little higher than at 445 deg.

The explanation of this phenomenon with iron is as follows: While the decomposition, in the presence of nickel, cobalt, and iron at low temperatures, occurs according to the equation $2CO = CO_2 + C$, the iron, at temperatures of 445 deg. C. and 508 deg. C. enters itself into the reaction. It is oxidized and reduces the CO_2 according to the equation $Fe + CO_2 = FeO + CO$. The CO, formed in this way in the presence of fresh metallic iron, is decomposed again. These reactions continue until nearly all the gas has disappeared. The CO which was present at the beginning is then almost all decomposed, its carbon precipitated, and its oxygen bound to iron. This proves that carbon monoxide under these conditions being converted into CO_2 is really an oxidizing agent for iron.

The dual influence of the iron, viz.: that it first acts as a catalyser to bring about the reaction $2CO = CO_2 + C$, and then secondarily enters itself into the reaction as soon as the CO_2 concentration is high enough, may have a great influence on the efficiency of an iron-reducing furnace. As soon as the CO_2 concentration exceeds a certain limit, the gas will not only be unable to reduce FeO to metal, but will even reoxidize iron which may have already been reduced, and, in this way, bring about the contrary of what is intended, viz.: oxidizing iron to oxide instead of reducing oxide to metal.

I might add that, in order to see to which point CO can act oxidizing, Professor Schenck and Dr. Heller undertook a great number of determinations. They used two methods:

First.—They allowed CO, at constant temperatures, to act on finely divided iron and determined the pressure at which the reaction came to a finish.

Their second method was to mix ferrous oxide with carbon and to heat the same to constant temperatures. The reduction took place with development of CO and CO_2. The development of gas stops after the pressure of the total equation is reached. For both methods, they used a quartz tube, which was connected with a glass manometer

The results of both methods were the same, and they were able to prove that CO is only able to act oxidizing up to a temperature of 780 deg. C. Above this temperature, CO can only act reducing.

By these experiments, they proved that metallic iron only enters into the equation of CO, CO_2 and C below 780 deg. C., while above this temperature it does not react any more with CO.

This reaction, $2CO = CO_2 + C$, in the presence of metallic iron at low temperatures, also explains the clogging up of the furnaces in which CO is decomposed in the presence of metallic iron. This will, for instance, take place if a furnace, in which iron has been reduced at higher temperatures, suddenly cools off and CO comes in contact with this metallic iron.

This investigation, of course, is by no means complete as to all the reactions that are taking place in the blast furnace. These experiments were simply undertaken to study the decomposition of the carbon monoxide in the presence of metals. The other reactions that are taking place in the blast furnace, the equation between carbon, carbon monoxide and carbon dioxide at different temperatures and the action of these with different iron oxides have been investigated very completely, both theoretically and practically by Boudouard, Schenck, Baur, and Glaessner.

Indigo White.—Electrolysis is used in a French process of Henri Chaumat, of Paris, to reduce indigotine to indigo white. The process is carried out in a bath of alkali carbonate protected from the air. The anode is carbon and the cathode indigotine. The latter is in form of a powder, which may be agglomerated with powdered graphite or other good conductor of electricity. Under the influence of the electric current hydrogen is formed at the cathode reducing the indigotine and producing indigo white which dissolves in the alkali simultaneously produced, forming a dyeing solution.

Production of Aluminium as a Laboratory Experiment.

By B. Neumann and H. Olsen.

It is peculiar that the methods of operation used in an industry which produces almost 2000 tons of metal per year are so little known that the production of this metal on a laboratory scale meets with difficulties. The two articles published in this journal during the past year on the production of aluminium in the laboratory confirm this remark.

The first detailed laboratory experiments have been published by Haber and Geipert,[1] who used a carbon crucible and employed a current of about 400 amp. M. deKay Thompson[2] could not, however, obtain satisfactory results when employing the method described by the above authors. He used a cell of graphite plates, and a subdivided anode and employed currents up to 1000 amp. The arrangement of Tucker,[3] who used a conical graphite crucible, can hardly be considered an advance over former apparatus.

We have also tried to make aluminium on a laboratory scale and have endeavored to imitate as much as possible the conditions of large-scale practice. The results of our experiments are given in the following article.

Process Used in Practice.

A photograph of an aluminium cell has been published only once, as far as we know, by J. W. Richards[4]; the cell shown is evidently a cell of Charles M. Hall, as used some years ago. The illustration shows 20 round anodes in two parallel rows in a high iron box. Quite detailed notes illustrated by sectional diagrams were given later by Winteler.[5] The cells described by Winteler are also rectangular and are also provided with double rows of carbon electrodes. More recently circular cells have been introduced, the anodes being distributed over the whole surface.

The aluminium cells are simple reinforced wrought-iron boxes on the bottom of which there is a series of carbon plates. The bottom plate acts as cathode at the start of electrolysis; the aluminium which is set free collects on the carbon plate and then acts itself as cathode. The reason of covering the bottom with carbon is that at higher temperatures aluminium alloys with iron; further, in the beginning, when the mixture of cryolite and alumina is molten by means of a carbon resistor, the local heat effect may easily be excessive, so that the iron bottom would be burned through.

The cell is made so wide that the walls do not come into direct contact with the molten bath, but are completely covered with a layer of solidified charge. The size of the cell depends on the current. For a current of 8000 amp the cells have a length of 1500 mm (4 ft. 11 in.), a width of 1000 mm (3 ft. 3 in.) and a height of 400 mm to 500 mm (1 ft. 4 in. to 1 ft. 8 in).

In each cell there are 6 to 12 carbon anodes, which are suspended from insulated supports.

Formerly carbon blocks of about 100 sq. cm (15.5 sq. in.) cross-section and 1 m (3.28 ft.) length were used and current densities of 3 amp to 5 amp per square centimeter. The distance of the anodes from the walls was 15 cm (6 in.). The distance of the different anodes from each other was 10 cm (4 in.). If the distance is less the anodes are liable to rapid destruction and carbon particles fall into the molten bath and foul it.

This disadvantage is now avoided by using very short electrodes with a much larger cross-section. Such electrodes are 40 cm (16 in.) high and have a cross-section of 35 cm x 35 cm (14 in. x 14 in.). The current density used is also lower, namely, 0.8 amp to 1 amp per square centimeter. Overheating of the bath is thereby avoided, but the bath remains quite fluid.

With the new short electrodes a relatively smaller voltage is lost in the electrodes. A disadvantage is the greater amount of anode scrap, but this is practically of no importance, since it is worked over again.

The method of supporting the cells is of great importance. Formerly the cells were placed free on insulated supports, the intention being to cool the walls and the bottom by contact with the air. An adjustable current of air was passed below the bottom. This method, of course, involved a great loss of heat and this had to be made up by the use of higher current densities. In modern practice the cells are not free, but enclosed, although some free space is left to permit the passage of an adjustable air current for cooling the bottom and sides.

The most suitable composition of the charge is a mixture of 80 per cent to 90 per cent of cryolite and 10 per cent to 20 per cent of alumina. Formerly some per cent of sodium chloride were added to reduce the melting point. The purity of the raw materials used is of great importance; any iron or silicon present are especially deleterious since they pass into the final product and deteriorate the physical and electrical properties of the aluminium. It is well known that it is impractical to refine aluminium afterward.

The voltage of a cell is about 6 volts, but depends considerably on the distance between anode and cathode. A low voltage is an indication of a correct composition of the charge. If there is not sufficient alumina in the charge the voltage rises.

The mixture is fused by inserting between the carbon bottom and each anode a little rod of carbon and heating it to white incandescence. When the charge is molten the carbon resistors are removed and the anodes are lowered into the bath. The temperature of the bath should be such that the color is about dark cherry red. On the surfaces of the bath crusts are constantly formed, which must be broken from time to time.

Former Experiments.

Haber and *Geipert* use a hollow carbon block as cathode and furnace, a movable carbon anode being suspended from above. The inside diameter of the circular hole was 11.3 cm at the bottom and 13.8 cm at the top; the depth was 7 cm. The diameter of the electrodes was 6.6 cm, the cross-section, therefore, 34.2 sq. cm. The use of a turned carbon block is not very advantageous for this purpose, because cracking of the block cannot be avoided. In two experiments artificial cryolite was used; in the third experiment natural cryolite. The charge consisted of 1000 grams of cryolite and 200 to 300 grams of alumina.

Haber and Geipert fused the mass by means of an arc and then started the electrolysis with 7 volts and 400 amp. The use of the arc for melting the charge is unsuitable because quite a quantity of cryolite and aluminium fluoride evaporate and because the arc causes the formation of aluminium carbide.

The experimenters did not pay special attention to the anodic current density, although this is of greater importance than the cathodic current density. Since the average current was 310 amp to 336 amp, the anodic current density was about 10 amp per square centimeter. That is much too high, and this is the reason why the anode was always consumed so as to form a sharp point.

The statement that the color was bright red shows that the temperature was too high. This is easily understood if 300 amp and 8 volts were used for 1200 grams to 1300 grams of charge. The amp-hour efficiency was 54.3 per cent. 44.84 per cent and 43.56 per cent.

M. deKay Thompson tried to reproduce exactly the experiments of Haber and Geipert, but the amp-hour efficiency obtained by him was only 38 per cent; the temperature of the bath was found to be 1100° C.; the voltage 10.5 to 12.5. The charge in the crucible soon became darkened and contained graphite. Then the anode effect occurred.

Another experiment was made in a box of graphite plates

[5] *Aluminium Industrie*, 1903 (published by Vieweg & Sohn, Braunschweig).

1.9 cm thick; the area of the bottom was 17.8 cm x 17.8 cm; the anode consisted of four graphite plates in the form of a grid 12.5 cm in height, breadth and length. The current used was, first, 500 amp, and later 900 amp to 1000 amp. The temperature of the bath was approximately 1000° C. The amp-hour efficiency was 49 per cent. The voltage was between 9 and 10.

Thompson was the first who mentioned the phenomenon of the anode effect, which occurred always after working for one-quarter of an hour or for half an hour, even when he repeated Haber's experiments. The current density used by him with the divided anode was much too high, namely, about 10 amp per square centimeter.

Tucker used a conical crucible turned from a 12.5-cm diameter graphite rod. The diameter of the conical hole was 12 cm at the top and 3 cm at the bottom and a graphite electrode, with a diameter of 3.15 cm, was the anode. He also fused the charge by means of the arc. He employed a mixture of cryolite with 15 per cent alumina, and used a current of 325 amp at 10 volts to 12 volts. The anodic current density was 28

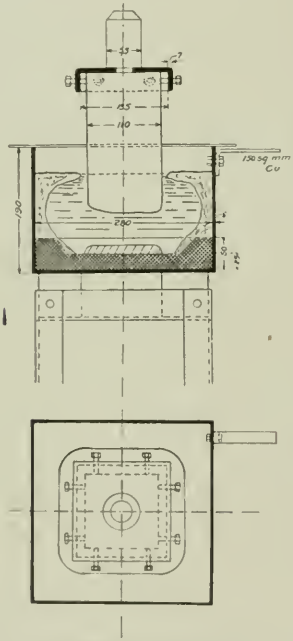

FIG. 1.—FURNACE CONSTRUCTION.

amp per square centimeter. The anode was quickly destroyed. This method seems unsuitable.

Experiments of the Authors.

1. **Furnace Construction, Electrodes.**—In order to imitate as much as possible large-scale practice, we used similar furnaces. All our furnaces were made of wrought-iron sheets and had a bottom plate of carbon. A copper bar was screwed to the iron box to make the connection to the circuit. The bottom carbon plate was firmly pressed against the bottom by means of screws. The various furnace designs employed differed only by form and size.

We used in our experiments a direct-current machine which gave 300 amp at 14 volts. But it could be easily so connected as to give 150 amp at 28 volts. This was quite an advantage for our experiments. The furnace dimensions were so chosen that the whole current of the machine could pass directly through the cell without use of series resistances. The most suitable design for this purpose was a simple square box of 5-mm wrought-iron sheets, which were welded at the edges, the bottom surface being 28 cm x 28 cm and the height 19 cm. An Acheson graphite plate was fixed to the bottom. Its thickness was increased later to 2.5 cm. This was found to be the best thickness.

The anodes were carbon blocks of smaller or greater size up to 14 cm x 14 cm cross-section. As shown in the illustrations, they are held by a wrought-iron head with the aid of copper sheets by means of eight screws.

The furnace box was placed on an iron frame and could be cooled at the bottom and at the sides by means of air or when necessary could be heated from the outside by means of burners. In the first experiments the fusion of the large quantity of powdered substance was quite difficult, so that the possibility of heating from the outside was at times quite an advantage. After we had gained some experience, it was no longer necessary to heat from the outside.

In order to melt the charge a hard carbon resistor of 6-cm length and 1.6-cm diameter was inserted between anode and bottom plate and heated by the current to white incandescence. In this way the mixed charge surrounding the carbon resistor was slowly fused. In the beginning the melting of the charge was sometimes not realized, because the anodes, which consisted of blocks of graphite, conducted too much heat away. This difficulty disappeared when we used hard-carbon blocks, which were furnished to us from the Plania Werke, in Ratibor. The graphite anodes are also easily destroyed during electrolysis, and the particles which dropped off spoiled the bath. It might probably be advantageous to make the bottom plate also of hard carbon instead of graphite.

We have also used smaller furnaces of 20 cm. diameter and less. The melting of the mass was quite successfully accomplished. But the small furnaces have the disadvantage that the charge is fused right to the walls of the iron box; during electrolysis as soon as the resistance near the bottom increases on account of undissolved alumina the current no longer passes to the bottom, but to the side walls.

2. **Observations During Operation.**—When melting a mixture of cryolite and alumina, care is to be taken to have the carbon always covered by the mixture, since otherwise the carbon would burn through at the place where it is uncovered. A charge which has already once been fused is more easily melted than a fresh powdered mixture. A charge of 12 kg requires about 3½ hours for melting. In this case a layer about 2 cm. thick around the walls remains unmolten.

In order to start electrolysis the anode is quickly raised, the carbon resistor is removed from the bath by means of an iron tongue and the anode is then suspended again into the bath. If the anode has the correct temperature, electrolysis starts at once. Graphite electrodes which are good conductors are cooled so easily that when the electrode is raised out of the bath it becomes covered with a thin layer of solidified charge and when it is again suspended in the bath only a small amount of current passes through the cell; the whole bath may then freeze. With hard carbons the danger is less.

When in our experiments the anode had accidentally cooled off too much (while taking it out of the bath in order to remove the carbon resistor) and when it was observed that the current decreased after the anode had again been suspended in the bath, we changed the connections of our machine, so as to run at the double voltage (28 volts); this overcame the trouble. The connections of the machine were then again changed and the electrolytic process took place absolutely quietly.

We have observed several times that in melting a fresh charge the carbon resistor was surrounded by a tube of a mixture rich in alumina which would not melt. The cause is probably to be found in the moisture in the charge. When thoroughly preheating the alumina the phenomenon did not occur.

The electrolysis was always very quiet in the large furnaces

The distance of the anode from the bottom plate was in the beginning 6 cm; later somewhat less on account of the reduction in volume of the charge. The anodes were regulated about every 30 minutes. During electrolysis (as is also the case in practice) a hard crust formed on the bath, which had to be broken for regulating the electrodes or for making additions to the charge.

With this relatively small cell the uniform solution of the alumina in the bath offered sometimes difficulties. Part of the charge added later often directly forms crusts and, therefore, does not get into the bath at all, so that the level of the bath falls. Sometimes the added charge also falls to the bottom of the bath without dissolving quickly enough, so that the alumina accumulates near the bottom and thickens the bath and increases the resistance. The amount of the addition of alumina was calculated on the basis of an average amp-hour efficiency of 50 per cent. One hundred amp-hours produce theoretically 33.7 grams of aluminium, so that with 50 per cent amp-hour efficiency only 16.85 grams are obtained, corresponding to the consumption of 31.8 grams of alumina. But as hardly all the alumina is dissolved, we used practically 40 grams of alumina per 100 amp-hours in mixture with the same amount of cryolite. When the electrolysis proceeded properly, the calculated amount of this mixture was added every thirty minutes. If there was trouble, either alumina alone or cryolite alone was added, according to the circumstances. An addition of aluminium fluoride was mostly unnecessary.

Whether the composition of the bath is correct, is well indicated by observing the temperature of the bath and the voltage. When the electrolysis has been going on for some time the aluminium deposited acts as cathode. In the beginning of our experiments we have melted several times a certain amount of aluminium on the supposition that this would facilitate the first deposition of aluminium, but we could not find any considerable advantage.

If some undissolved alumina deposits once on the bottom, all kinds of disturbances are experienced. The heavy layer presses the aluminium upwards, and the contact between the aluminium and the bottom plate gets poorer. Or the metal no longer covers the whole surface, but only a part, and therefore grows toward the anode, whereby an overheating effect is produced. By stirring the bath and ladling out the aluminium the difficulties can be overcome.

The occurrence of the anode effect mentioned by M. deKay Thompson has been observed by us also occasionally. The anode effect is due to the fact that the anode is no longer wetted by the bath. It seems that the anode is surrounded by a gas layer, small arcs passing over between anode and bath. On account of this transition resistance the voltage increases by several volts. Fluorine is then set free at the anode.

According to our observations the anode effect occurs if the anodic current density is too high, say, more than 4 amp per square centimeter. This phenomenon also occurs when large anodes are irregularly consumed. The composition of the charge, however, also plays a part. The less the content of fluorine in the bath the more often does the anode effect occur. By quickly opening and closing the circuit, this trouble can be overcome.

Occasionally an ill-smelling gray layer of molten metal is found on the bottom; in contact with water this metal evolves a gas which consists mainly of hydrogen. We could not prove the presence of aluminium carbide. The gray color is caused by a metallic mist of very finely divided aluminium.

In the following we give the details of two different experiments; in one case trouble was experienced, while the other experiment was absolutely quiet.

A.

12 kgs. of charge, consisting of 10 per cent alumina and 90 per cent cryolite; cross-section of anode 80 sq. cm.

Eighty grams charge were added at 1.45, 160 grams charge at 2.05, 200 grams charge at 3.00, 30 grams alumina were added at 3.20 and 100 grams cryolite at 3.40.

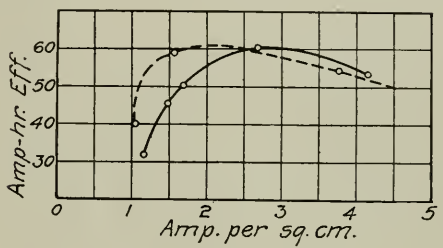

FIG. 2.—EFFICIENCY CURVES.

The experiment was then stopped on account of the anode effect. The anode was finally so much corroded that the anodic current density had increased to an amount which produced the anode effect.

The time of the electrolysis was three hours and forty minutes, the average current 214.5 amp, so that 778.5 amp-hours had been consumed, which should have yielded theoretically 265 grams of aluminium. The output was in reality 161 grams of aluminium, so that the amp-hour efficiency was 60.8 per cent. The current density was 2.68 amp per square centimeter.

B.

12 kg. of charge, consisting of 10 per cent of alumina, 10 per cent of sodium chloride, and 80 per cent of cryolite.

Anode surface 11 by 11 cm = 121 sq. cm.

Melting, 3 hours 40 minutes.				
11.00 } 2.40 }	300	amperes	7	volts
Electrolysis	60	grams aluminium added.		
2.40	200	amperes	14.4	"
3.00	200	"	9.0	"
3.30	200	"	9.0	"
4.00	200	"	9.0	"
4.30	200	"	9.0	"
4.50	200	"	9.0	"
5.10	160	"	9.2	"
5.30	160	"	9.2	"
5.45	160	"	9.2	"
6.10	150	"	9.4	"
6.30	150	"	9.4	"
7.00	150	"	9.4	"

During this experiment 100 grams of the mixture of alumina and cryolite were added every 30 minutes. The experiment was interrupted because the current from the central station was disconnected. Seven hundred and eighty-five amp-hours had been consumed. The theoretical output should have been 266 grams, while 156 grams of aluminium were obtained in fact. The amp-hour efficiency was therefore 58.8 per cent. In this experiment 14.6 per cent of sodium chloride evaporated.

In another experiment the loss of fluorine was determined. There were in the beginning 50.26 per cent of fluorine in the bath, while after one hour's electrolysis the bath contained only 47.47 per cent, so that the loss was 2.79 per cent.

3. **Results of Experiments.**—In the following we give the results of a number of tests made with different anodic current densities:

Charge.	Anode surface.	Ampere hours.	Time of electrolysis.	Current density in amperes per sq. cm.	Ampere hour efficiency.
10% alumina and 90% cryolite	169 cm.	750	3 hrs. 50 min.	1.17	31.8%
	144	690	3 " 15 "	1.38	45.5
	121	875	4 " 15 "	1.70	49.8
	81	545	3 " 10 "	2.15	49.6
	80	778	3 " 40 "	2.68	60.8
	50.3	1010	4 " 50 "	4.15	53.0
10% alumina, 80% cryolite, 10% NaCl	169	685	3 " 45 "	1.08	40.0
	121	785	4 " 10 "	1.57	58.8
	50.3	336	2 " 5 "	3.12	53.9
	50.3	373	2 " — "	3.72	54.2

If these results are plotted graphically it will be seen that the amp-hour efficiency is a maximum for an anodic current density of 2 amp per square centimeter. On the other hand, the results are very poor with a current density of 1 amp per square centimeter. But this does not agree with the results from operation on a large scale. It should not be forgotten, however, that in experiments with electric furnaces the conditions in the laboratory furnace are very different from the conditions in the large commercial furnace, and that in the latter the losses from conduction and radiation can be made very much smaller. An anode which is too large, such as is used in our experiments, with a current density of 1 amp per square centimeter, carries off so much heat that the bath cannot be maintained at the proper temperature. The above results are, therefore valid only for our design of furnace and are not valid in general. The best amp-hour efficiency which we obtained was 70.4 per cent with a current density of 2 amp per square centimeter.

From the diagram of Fig. 2, it is seen that an addition of 10 per cent of sodium chloride exerts a beneficial influence only with small current densities, while with higher current densities the bath which contains no sodium chloride gives better results.

Some experience is required to carry out successfully the experiments. In the beginning we experienced difficulties especially in melting the charge. In such cases it is to be recommended to cover the side walls of the iron box, and perhaps also the upper portion of the anode, with asbestos board to reduce the radiation loss and to heat the bottom of the box with gas burners. Much time is saved in this way. It is also to be recommended not to select at once too big an anode for the first experiments.

Elektrochemisches Institut, Technische Hochschule, Darmstadt, Germany.

Chilling or Heating Action of Furnace Electrodes Versus Least Electrode Loss.

By Carl Hering.

In determining the proper proportions of electrodes for furnaces, the choice may sometimes arise between allowing the loss in the electrode to be slightly greater than the least possible, or allowing the electrode to slightly chill or heat the product in the furnace; either may be adopted at a sacrifice of the other. The difference is due to the variations of the conductivities with the temperature.

The purpose of the present article is to discuss this choice from the standpoint of the designer and constructor of furnaces, and to analyze in a general way the underlying principles, believing that the results of such an analysis may be of some use as a guide in determining what the best proportions are for any given conditions, either by showing how to take account of these factors or by showing that they may be neglected.

In the writer's earlier papers* it was shown that when the variations of the conductivities with temperature can be neglected, the conditions under which there will be no chilling of the furnace product by the electrode are identical with those for the least possible loss of energy in the electrodes. And that the conditions for the latter also correspond with those for the avoidance of excessive temperatures (higher than those in the furnace) within the furnace walls.

While any further corrections in these useful general results, due to the variations of the conductivities with the temperature, are probably too small to require attention in practice, and that, therefore, the writer's simplified solutions will probably suffice in most cases, yet the question has been raised as to the effect of these variations and much stress has been laid on them by others, much more, in the writer's opinion, than is warranted by their small importance. But as it was not known what the effects were, or how large they were, it left an uncomfortable uncertainty.

The purpose of the present article is to endeavor to show the nature of these, more with a view of clarifying the situation than to lay any stress on their importance; on the contrary, it is believed that it will rather tend to show that we may be content to neglect the quantitative effects of these troublesome temperature variations in ordinary practice; or when greater accuracy is required, it will show in what direction the allowances for these corrections should be made.

Dr. A. E. Kennelly, in a very able and interesting paper* was the first, and so far the only one, to demonstrate that these variations give rise to only slight differences between the law for the minimum loss and that for no flow of heat to or from the furnace—that is, the two laws are then no longer quite identical. This will also be seen to be made evident by following out the new method of analysis used in the writer's article in the March issue of this journal, page 128, on "Properties and Behavior of Furnace Electrodes," to which the reader is referred for a further description of the method to be used below.

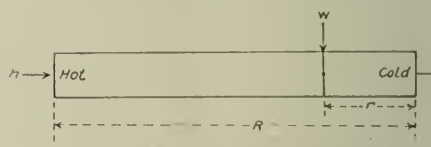

Fig. 1.—Center of Gravity of Electrode.

In the adjoining Fig. 1, which represents an electrode, let it be assumed that the material, carbon, for instance, has a falling temperature coefficient, in which case the colder half will have the greater resistance; hence, the greater half of the watts will be generated in this half. The center of gravity of this uneven distribution of the generated watts will, therefore, be to the right of the middle, as shown by the point of the arrow. It may, therefore, be assumed for the present purpose that all the watts w are generated in the section drawn through this center of gravity at the arrow marked w.

It was shown in the article in the March number, just referred to, that the number of watts necessary to keep any heat from flowing from the furnace—that is, to prevent all chilling action by the electrode, increases as this center of gravity is nearer to the cold end; if it were quite near, the number of watts would be extremely high, hence the loss very great.

It hardly requires an algebraic analysis to show that in such

* This journal, October, 1909, Vol. VII, p. 442, and revised and enlarged in *Trans. Am. Electrochem. Soc.*, Vol. XVI, p. 265.

* "On the Modifications in Hering's Laws of Furnace Electrodes Introduced by Including Variations in Electrical and Thermal Resistivity." Proceedings Am. Inst. Elec. Eng., March, p. 267.

a case if the section be increased somewhat it would reduce the number of watts generated by that same current, and in the same proportion, hence it would reduce that part of the total loss which is due to the resistance. This increase in section would, however, cause some heat to leave the furnace—that is, it would cause some chilling action. But as the latter would be small, while the reduction in the former would be relatively large, it follows that the total loss would be diminished.

Hence, without any intricate algebraic analyses, it is evident that with carbon or any other electrode material having a decreasing resistivity for an increase of temperature, the total loss could be diminished, if desired, by making the section somewhat larger than that required for no flow of furnace heat, and allowing it then to chill the furnace somewhat. The designer has his choice between the two evils. An increase of size is an evil in this case because carbon electrodes are in general already undesirably large in section before this increase is made.

In making this choice it must be remembered that a chilling action of the electrode signifies that the capacity of the furnace is reduced thereby, and it must be considered whether the gain in a smaller loss is worth this reduction in the capacity of the furnace; in general, it probably will not be. One of the chief advantages in proportioning electrodes as recommended in the writer's earlier papers, is that the capacity of the furnace may thereby be raised to its full extent.

The physical meaning of this action of carbon is that it is more economical in power to send some of the energy in the form of electricity through the whole length of the electrode into the furnace and then let it flow back again and out at the cold end, its original entrance, in the form of heat. In other words, such an electrode allows electrical energy to flow more freely in one direction than it allows the same energy in the form of heat to flow back in the other direction. It is an action somewhat analogous to a leaky valve.

With electrode materials like iron, on the other hand, which have a rising resistivity, a similar argument shows that the total loss could be reduced also, but in this case the center of gravity is nearer the hot end, and the section must therefore evidently be decreased. Hence, instead of chilling the furnace product by this change, the flow of heat would now be from the electrode into the furnace—that is, with iron electrodes it is possible not only to reduce the former minimum loss, but, in addition, to actually send more heat into the furnace than it did before when the loss was greater. It is no longer a choice between two evils, but a double gain. The attending objectionable feature, however, is that somewhere within the walls there will then be generated a higher temperature than in the furnace itself.

While it is evident that by making such changes in the section the total loss may be decreased, it is also evident, when this change of section is greatly exaggerated, that the total loss will again increase and become much greater than it was originally. This means that there is a certain section at which the loss is a minimum.

The amount of this change of section to reduce the loss to a minimum, of course, will depend upon how far the center of gravity is from the middle; the farther it is, the more will be the possible reduction in the loss. This means that the greater the change of the resistivity with the temperature, the greater will be the reduction of power loss which becomes possible by operating at a minimum loss instead of with no chilling action and with no high temperatures within the walls.

As stated above, this possible change of section therefore depends on the shifting of this center of gravity; if there is none, the conditions of minimum loss will correspond with those for no flow of heat, as in the simplest case discussed in the writer's earlier papers. If the position of this center of gravity is given by n so that $n = R/r$, in which R is the total thermal resistance and r that from the center of gravity to the cold end; and if a represents the change of cross-section necessary to change from the condition of no flow at the hot end when the section is S, to that of minimum loss when the section is s—that is, if $a = s/S$; then it can be shown that for a minimum loss $a = \sqrt{n-1}$. The proof of this law for the minimum is given below.

To illustrate this with examples, suppose $n = 4$, that is, $r = 0.25\,R$, which is believed to be a very exaggerated case, probably far beyond any that would occur in practice. It means that the center of gravity has been moved one-half the distance from the center to the cold end, if the thermal conductivity is uniform, or, if not, then to such a distance that the thermal conductivities are in that proportion. Then $a = 1.73$, that is, the new section would be almost twice as large.

Let W equal the loss for the original section when there was no flow of furnace heat. From the formula (11) given below, the minimum loss will now be $0.866\,W$, or only 13.4 per cent less than before. The generated watts w are now, from (2), equal to $0.577\,W$, or a little over half as much as before. The loss of heat h from the furnace now is, from (10), equal to just half of w, or $0.289\,W$—that is, over a quarter as much as the total loss was originally. As a check, the total loss now is the sum of w and h: namely, $(0.577 + 0.289)\,W = 0.866\,W$ as before.

Hence, even under greatly exaggerated conditions, the gain in power loss by making this change would be only 13.4 per cent, and this involves almost doubling the size of the electrode and a loss of furnace heat equal to over one-quarter of the original total loss, which would be quite likely to chill the furnace appreciably, thereby reducing its effective size. Under ordinary conditions it would therefore probably not be worth while to make this correction due to this change of resistivity.

Let it now be assumed that the resistivity rises and to such an extreme extent as to bring the center of gravity half way to the hot end. The results, calculated in the same way, now are $n = 4/3$, $a = 0.577$, $w = 1.732\,W$, $h = -0.866\,W$, and total loss $0.866\,W$. Hence, in this case the saving of power would again be 13.4 per cent, the size of the electrode would be reduced to nearly one-half, and the generated watts would be nearly doubled, but just half of them would now flow into the furnace, thereby contributing heat to it instead of chilling it as before. This would be a gain in all features, except for the fact that a higher temperature than that in the furnace would be generated within the walls. Whether this is a disadvantage depends chiefly on the temperature conditions. In a low-temperature furnace for tempering castings, for instance, it might perhaps be taken advantage of.

In making the above corrections due to the temperature coefficients, the change of section would bring about slight changes in the temperature gradients, and it will be found that these in turn react to again reduce the advantages of the change somewhat. Hence, the exact gains would be even less than the small ones given by these formulas.

This correction involves both conductivities; hence, a material like graphite, which has a slightly falling electrical resistivity and a rapidly falling thermal conductivity, would presumably act in this respect like a material with a rising resistivity—that is, like the metals and unlike carbon.

The general conclusions of the present investigation, therefore, are that, in general, these corrections are too small to be considered in practice, and that the engineer need consider them only in so far that when the material has a falling resistivity (like carbon) he had better make the section a little larger rather than smaller, and when the material has a rising resistivity he may feel safe to make the section a little smaller than the simple formulas require. This lack of importance of these temperature corrections is indicated in the writer's earlier papers by the flatness of the minimum curve, as was described at that time.

PROOF OF THE LAW.

Let W = watts generated in the electrode when there is no flow of heat through the hot end.

w = watts generated in the electrode when the total loss is least.

h = actual flow of heat through the hot end when the total loss is least.

X = total minimum loss.

a = the ratio of the section for minimum loss to the section for no flow through hot end; that is, the proportion in which the section for no flow at furnace must be increased or diminished to give the section for minimum loss. The length is assumed constant.

R = thermal resistance of whole electrode.

r = thermal resistance of the part from the center of gravity of the watts to the cold end.

n = the ratio of these two thermal resistances, that is R/r.

T = total temperature drop in the electrode.

Let all the values be known for the condition that there shall be no flow of heat through the hot end. Hence, W is known. These are determined by the laws given in the writer's previous papers, when the constants used are those determined by the method therein described,* in which they are based on the conditions of no flow at the furnace end. Now let it be required to find how much larger or smaller the section should be made in order to reduce the loss to a minimum. This increase or decrease of section is represented by the ratio a.

It is evident that when the section is now changed, the current and, of course, the temperature drop being the same, there will always be some actual flow of heat through the hot end; this is represented by h; when the section is increased the flow will be from the furnace, that is, h will be positive; when the section is decreased, it will be from the electrode into the furnace, that is, h will be negative. Attention is here called to the fact that in the present discussion h represents the actual flow of heat and not that which would flow if there were no electric current.

The total minimum loss is now the sum of that generated electrically in the electrode and that flowing from the furnace; hence

$$X = w + h \qquad (1)$$

in which w and h are to be determined.

The value of w will, of course, vary inversely with the section; hence,

$$w = W/a \qquad (2)$$

But the value of h is not so easily determined. The electrical analogy again indicates the solution. If an electric current h enters one end of a conductor, as in Fig. 1, and another, w, enters somewhere between the ends, the two joining and flowing out of the other end together; then if the condition is that in all cases the drop of potential T between the two ends is always the same, the relations between these two currents are readily found as follows:

The total drop of potential T will be the sum of that in the first part, where h is flowing alone, plus that in the second part where h and w flow together. Hence, if R is the total resistance and r is that of the second part, then

$$T = h(R - r) + (h + w)r = hR + wr \qquad (3)$$

This applies equally well to thermal currents and in this equation the letters for the corresponding thermal quantities have been used; it, therefore, represents the thermal relations

In the original electrode, in which there was no flow of furnace heat, h, this quantity h is zero; hence, if r' is the thermal resistance of that part of that original electrode between the center of gravity of the generated watts and the cold end, then

$$T = Wr' \qquad (4)$$

As the difference of temperature T between the two ends is the same for both, these two expressions may be equated, and if at the same time they are simplified by substituting

$$n = R/r \qquad (5)$$

and

$$r' = ra \qquad (6)$$

the final result reduces to

$$h = W(a - 1/a)/n \qquad (7)$$

Hence formulas (2) and (7) will give the values of the watts w generated electrically and the flow of heat h out of or into the furnace through the hot end, when the value of a is known for which the total loss will be least. It is evident that some such value of a must exist, because if the section be either increased or decreased greatly it is easily seen that the total loss must increase; hence, if it increases in either case there must be some value for which it is least.

To find this, the calculus must be resorted to, but the solution is extremely simple. The total loss X is always the sum of w and h (remembering that h here is the actual flow while the electric current is flowing, and not the flow when there is no current). Hence,

$$X = w + h = W/a + W(a - 1/a)\,n = W/n \quad \left(a + \frac{n-1}{a}\right) \qquad (8)$$

Differentiating this and placing the first differential coefficient dX/da equal to zero, gives, after reduction, the very simple relation

$$a = \sqrt{n - 1} \qquad (9)$$

which is that value of a which will make X a minimum.

Hence the change a in cross-section necessary to change over from the condition of no flow through the hot end to that of minimum total loss is very readily found from the known value of n.

Knowing this value of a, all the other quantities are easily calculated. The new generated watts, w, are found from the simple formula (2). The flow of furnace heat h may be found from formula (7), but by combining it with (9) and (2) it reduces to the simpler forms

$$h = \frac{W}{a}\left(\frac{n-2}{n}\right) = w\left(\frac{n-2}{n}\right) \qquad (10)$$

which latter also shows the relation of h to w. When this value becomes negative it means that heat is flowing from the electrode into the furnace—that is, there is a high temperature point in the electrode.

The total minimum loss is the sum of w and h, and is given in formula (8), but it may now be reduced to the more simple form.

$$X = \frac{2aW}{n} \qquad (11)$$

It might be of interest to state that when $n = 2$, that is, when the center of gravity is in the middle, the formulas all give the same results as in the writer's original paper, as, of course, they should.

Conclusion.—Incidentally, the present investigation is a good illustration of the recommendations of certain distinguished scientists, namely, that it is best to solve a new problem first under the simplest possible conditions, leaving the refinements to a second or third approximation, if indeed these refinements are necessary at all. This is the practice which the writer has endeavored to follow in his solution of the electrode problems and it has led to simple results which are thought to be amply sufficient for all practical purposes.

Near Alloys.

In the issue of Feb. 22 of *Metallurgie* Prof. K. Friedrich, of the Institute of Technology of Breslau, Germany, makes the following interesting and suggestive remarks:

Thermal research work of the last decades has proved that the melting and freezing process of an alloy does not occur at a certain fixed temperature, but takes place within a wider

range of temperature. This at least is the rule. Exceptions are the case of the end constituents of the alloys, viz., the pure metals, the chemical compounds, and finally certain solutions to which belong the eutectics and those compositions for which the curves of crystal mixtures show a minimum or maximum.

Within this freezing or melting interval, the extension of which depends on the ratio of the quantities and the nature of the constituent parts, the alloy consists of a molten and a solid portion. If the former is in excess we have a fused bath in which crystals are floating, while if the latter is in excess we have crystals impregnated with liquid drops. If we select a proper ratio of the constituents we can produce a substance which is plastic and can be kneaded. Now let us add materials of a higher melting point, work them into our dough-like substance, let us mix the mass more intimately, perhaps by means of a certain pressure, let us cool it, and we will get a product which is not yet known in practice, namely, an alloy closely interspersed with foreign substances, without having had before a homogeneous solution.

Professor Friedrich mentions the following two examples from his laboratory practice:

He makes an alloy of 90 parts by weight of tin and 10 parts by weight of copper, fuses the two substances together by heating to about 500° C., and cools to about 220° C. In this neighborhood is the eutectic point. By proper regulation of the temperature (which in this case is not difficult, since the melting interval extends to about 450° C.) he obtains a dough-like mass. He now adds the foreign substance, which may be particles of light-blue cobalt silicate, the size and quantity of which is left entirely to his judgment. He kneads it all at a constant temperature, finally using pressure, so as to get it into the desired form. He then cools it, grinds and polishes it, and thus obtains a product which shows blue interstices in a white metallic field in a fairly uniform distribution.

In his second example Professor Friedrich begins with a mixture consisting of 98 parts by weight of lead and two parts by weight of antimony. First, he forms the alloy and then cools it until the eutectic temperature—about 250° C.—is reached. The mass is dough-like. He now adds iron filings; 10 parts by weight can easily be introduced. This is followed by mixing and pressing. The result is a kind of hard lead.

Are the products thus obtained true alloys? "Alloys in the fused state are essentially solutions of two or more metals or metalloids in each other."[1] They are produced from their constituents by fusing them together, therefore, by formation of a liquid solution. That is the rule. Where other modes of procedure have reached practical importance they are based at least on the tendency of the materials concerned to enter into solution. We may call attention to the process of diffusion of carbon into solid iron low in carbon if this iron is in direct contact with carbon or carbonaceous substances.

With our products there is no necessity that the substances employed are soluble in each other. Our products are, therefore, not true alloys. They are alloy-like structures, metallic compositions, near-alloys or whatever we may call them. At all events they are but mechanical mixtures. As far as known, such mixtures have not yet found any application in practice. They have been produced, however, before, especially by Spring,[2] who pressed powdered solid metals together under high pressure. This does not result in genuine alloys, as was said of Spring's experiments, but simply in mixtures as proved recently by Masing.[3]

Professor Friedrich's method differs from the method of Spring in that he does not start from solid metals, but from a dough-like substance. This means an advantage over Spring's process. The use of the substance in the dough-like condition permits the production of intimately mixed mixtures without employing very high pressures. The added particles can be rather coarse grained.

Of course, the dough-like condition is limited to a certain, and often brief, range of temperature. It is, therefore, necessary not only to heat the mixing and pressing devices, but to regulate the temperature exactly. With small quantities the latter condition is easy to fulfill by employing electric heating. But even with larger quantities the temperature may be maintained constant in practice without any great difficulty. Professor Friedrich draws attention to the Pattison process, where in a proportionately large kettle a silver-lead bath can be kept for one or two hours at a temperature of about 300° C. within 10° or 15°.

As to the properties of these new near-alloys it is, on the one hand, a disadvantage that they are only mechanical mixtures, but, on the other hand, it is an advantage that we are almost perfectly at liberty to select the material to be added. The only limitation is that the added substance remains solid and unaffected at the temperature of the mixture.

To go into details Professor Friedrich admits that in regard to tenacity, toughness, resistance against chemical influences, and good thermal and electric conductivity his near-alloys can hardly compete with genuine alloys even if a strong pressure has been employed in their preparation. For it would be exceedingly difficult to produce a mechanical mixture with such an intimate intermingling of its constituents as in an alloy that has been produced from homogeneous liquid solution.

The greatest disadvantage is that it is impossible to cast the near-alloys. On this account they cannot be used for many purposes.

On the other hand, with our near-alloys, we have the possibility of making metal-like substances perhaps of an especially low thermal and electric conductivity, since we can add to the fundamental alloy oxides, silicates, and, in general, poor conductors.

Further, the hardness of the near-alloys can be adjusted to much greater nicety than has been possible heretofore. Quartz, corundum, carborundum can be embedded in alloys. In a lead-antimony alloy iron may be embedded and its hardness adjusted exactly to that of the material of the axle.

The greatest field of usefulness of these near-alloys would be, according to Professor Friedrich, the production of "terrazzo"-like mixtures with a metallic base, as well as articles for general usage and for decorative purposes with peculiar color effects. As substances to be added there are at our disposal precious metals, artificial and natural minerals, especially precious stones, further enamels and glasses. Besides the tin-copper alloy mentioned above, silver-copper alloys would be also suitable as a starting material. For a composition of 90 parts by weight of silver and 10 parts by weight of copper the range of freezing temperature extends from 778° C. to 890° C.

Finally, the process permits perhaps the replacement of more expensive alloy constituents by cheaper ones. Professor Friedrich mentions the substitution of iron for antimony in hard lead, although in this respect the impossibility of casting the near-alloy is especially troublesome. But there might be left, or could be found, a small market anyway for this new kind of hard lead.

Altogether it is evident that near-alloys cannot enter into serious competition with genuine alloys. They are no full-fledged substitutes for the same, and can only be considered as of an inferior grade. But where they extend the present applications of alloys they may find use.

The Magnetic Properties of Electrolytic Iron and Some Commercial Steels.

By Charles F. Burgess and James Aston.

In connection with tests of the various properties of iron alloys made from electrolytic iron,* measurements were made of the magnetic quality. The results on certain of the binary

* Investigation of electrolytic iron and iron alloys made in the Chemical Engineering Laboratories of the University of Wisconsin under a grant from the Carnegie Institution of Washington.

series have been presented in several articles in previous issues of Metallurgical and Chemical Engineering. In these discussions it was pointed out that the primary material in the preparation of the alloys was electrolytic iron of high purity (99.9 + iron); and a common standard of comparison throughout all the tests was a bar forged from an ingot of electrolytic iron.

In this paper we are presenting data of tests made upon various samples of electrolytic iron, together with those upon the original anode material, indicating thus the effect of refining upon the magnetic quality. We have also embodied for comparison the results upon commercial samples of different degrees of purity.

Magnetic testing is not on such a basis at present that data of different investigators, at different periods of time and by different methods of testing, are strictly comparable. Even in the absolute ballistic method results are often markedly inconsistent; and comparisons of heterogeneous collections of data are likely to be misleading. All of our data, while open to the common objection to intercomparison, were obtained by the same operator upon the same apparatus, with every precaution taken, before any series of tests were made, to have consistent checking to a standard; the results, therefore, may be considered strictly comparable among themselves.

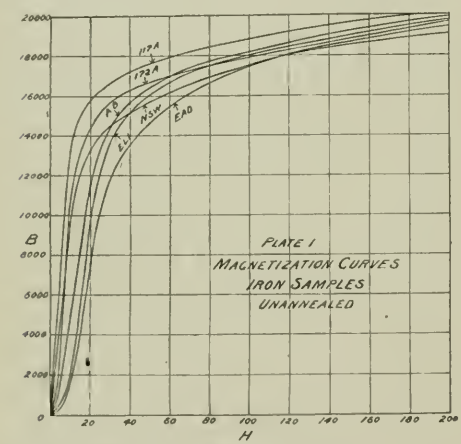

FIG. 1.—MAGNETIZATION CURVES. IRON SAMPLES. UNANNEALED.

Electrolytic Iron Tests.

Tests under four different heat treatments have been made upon the sample noted in the following table:

Bar	Character.	C.	P.	Si.	S.	Mn.	Fe.
NSW	—Swedish anode, forged	0.260	0.007	0.109	0.007	0.021	99.596

172A	—Electrolytic, melted and forged						

NSW is forged from one of the anode bars as used in the single refining tanks, and was bought for high-grade Swedish iron. The analysis indicates a somewhat high carbon content, but the material has the desirable quality of being very low in phosphorus, which is a troublesome element in the refining operation, as will be seen by examination of the phosphorus content of the refined bars. The indications are that all of the phosphorus had been carried over to the cathode, and the percentage content in the product increased because of the loss of iron in the slimes. However, it must be noted here that analyses of the double refined iron showed a phosphorus content of only 0.003 per cent. The analyses above show also the difficulty of preventing the absorption of carbon by the charges, due to the reducing action of the iron upon the carbon monoxide furnace atmosphere.

Bar EAD was cut from a heavy single refined cathode sheet without melting or forging (in fact, without any heating whatever) and is thus representative of the electrodeposited material. Bars 117A, AB, ELI, and 172A are made of electrolytic iron melted into ingots and forged into rods. For 172A, double refined material was used.

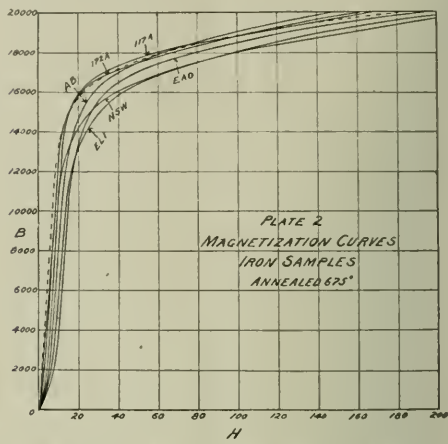

FIG. 2.—MAGNETIZATION CURVES. IRON SAMPLES. ANNEALED 675°.

The results of the tests are indicated in Tables I and II and in the curves plotted in Plates 1, 2, 3 and 4. In the unannealed condition, the forged electrolytic iron bars (117A, AB, ELI, and 172A) represent a considerable variation in relative quality. This cannot be ascribed to the difference in purity, as will be noted on comparison of the analyses. The differences are very likely due largely to the molecular condition of the samples, as

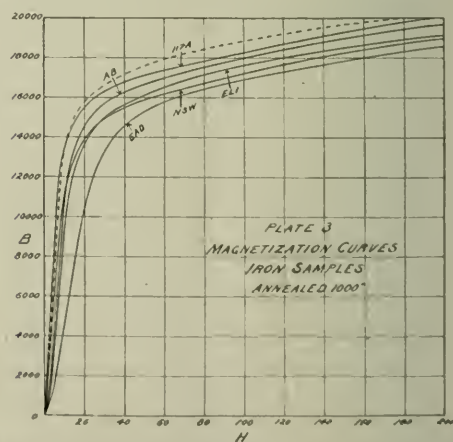

FIG. 3.—MAGNETIZATION CURVES. IRON SAMPLES ANNEALED 1000°.

a result of lack of uniformity in the forging temperature and to strains set up in working. Bars 117A and 172A are especially good, the former in particular being so uniformly good in the unannealed state and throughout the entire length of the curve that it was chosen as the standard comparison curve for all our tests.

The effect of successive heat treatments is seen by inspection

of the curves and tables. For comparison, the curve for 117A as unannealed is indicated by a dotted line. A marked improvement throughout the entire range of the curves is the result of heating to 675° and slowly cooling, due no doubt to the removal of all forging strains and the opportunity afforded for the grain size of the material to become normal. The improvement is most pronounced in the poorer samples of the unannealed tests (AB and ELI) and it is very slight in bar 117A, indicating, perhaps, that the forging treatment left it in practically its best molecular condition.

A second heating has been accompanied by an improvement of the quality in the lower ranges of the magnetizing force,

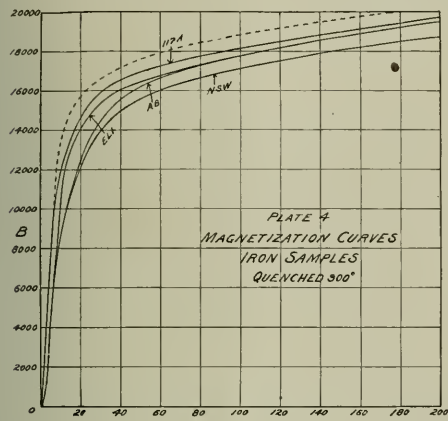

FIG. 4.—MAGNETIZATION CURVES. IRON SAMPLES. QUENCHED 900°.

but except for these ranges, the densities fall below those for the lower annealing temperature.

Quenching from a temperature of 900° C. has been accompanied by a deterioration of the quality for all magnetizing forces. This effect is most marked for the lower valves of H, but, all in all, it is very slight, indicating in a way the purity of the material, since, although the temperature was sufficiently high, the absence of carbon had prevented any hardening. This is more clearly brought out in Table II, where the coercive force and retentivity are indicated for the various treatments. The coercive force, indicative of the magnetic hardness, which in turn varies with the physical hardness, has become less under the successive heatings.

ment the superiority of this Swedish anode is less marked, even at low values of H; and in all cases, at higher values of the magnetizing forces (H above 20) the electrolytic curves reach higher maxima of density. Further annealing at 1000° C. has only served to increase the general effect just mentioned.

The influence of the carbon is most interestingly evident in

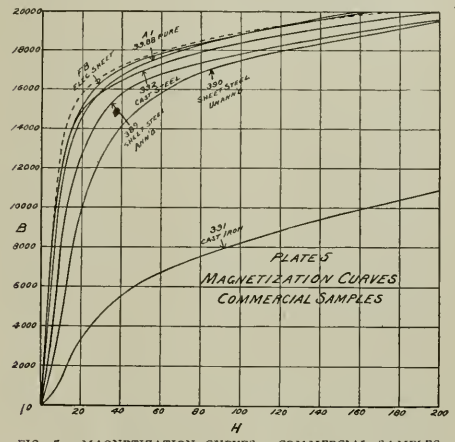

FIG. 5.—MAGNETIZATION CURVES. COMMERCIAL SAMPLES.

the following table, where the coercive forces are given after annealing at 1000° C. and again after quenching at 900°.

Bar.	Per cent, C.	Coercive Force Annealed, 1000°.	Coercive Force Quenched, 900°.
ELI	0.012	6.0	5.5
117A	0.047	3.1	2.5
AB	0.120	5.5	5.5
NSW	0.260	3.9	5.0

In this group of curves, one of the most interesting is EAD, made, as mentioned previously, from electrolytic iron as deposited, without melting or forging. In the original condition it may be classed as rather poor material, falling well below the other curves in the lower ranges of magnetizing force, and having the high coercive force of 18.5. After the first annealing, however, it has become very good material, taking a place in the midst of the others. The coercive force has fallen off to 9.3, or one-half of its former value, and the value of B for H = 20 has almost doubled, from 7300 to 13,250. The effect may be ascribed to the driving off of the hydrogen occluded in

The effect of the refining is indicated by comparison of the curves for bar NSW, the anode material, with those discussed above. Unannealed, and at lower magnetizing forces, it is very good magnetically; in fact, it excels two (AB and ELI) of the four refined bars. 117A and 172A are better, however, throughout the whole range of tests. After the first heat treatment the electrodeposition, and perhaps the allied alteration in crystalline structure.

Commercial Samples.

Included in Tables I and II and plotted in Plates 5 and 6 are the results of tests on commercial samples of types representing

varying degrees of purity. The descriptions of the materials are as follows.

Bar. Character.

A. I. High purity commercial iron, made by basic open-hearth process. Purity, 99.884; C, 0.030.
Sample cut from rolled bar and tested without heat treatment.

277. Commercially pure iron—composition and heat treatment unknown.

258. Norway iron—composition and heat treatment unknown.

131. Bessemer steel—composition and heat treatment unknown.

F. B. Sheet steel—made and treated especially for electrical purposes.

390. Second quality sheet steel from large electrical manufacturer—not annealed.

389. Same as 390, but annealed.

392. Cast steel used by large electrical manufacturer.

O. H. Open-hearth cast steel for electrical work.

CRU. Crucible cast steel from same source as O. H.

248. Tool steel.

391. Cast iron.

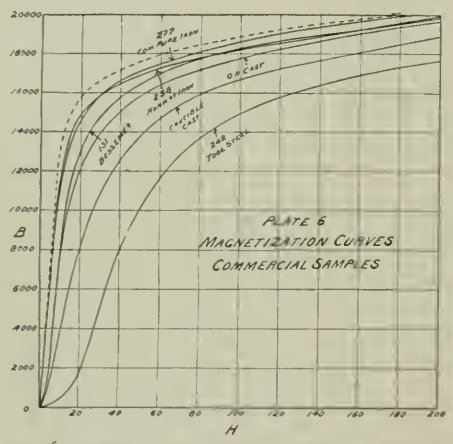

FIG. 6.—MAGNETIZATION CURVES. COMMERCIAL SAMPLES.

The direct comparison of these materials with the electrolytic samples can be made through the medium of standard 117A, which is shown on Plates 5 and 6 by a dotted curve.

TABLE II.—COERCIVE FORCE AND RETENTIVITY.

Bar.	Composition.	Coercive Force. H (MAX) = 200 Unannealed.	Annealed, 675°.	Annealed, 1000°.	Quenched, 900°.	Retentivity. H (MAX) = 200 Unannealed.	Annealed, 675°.	Annealed, 1000°.	Quenched, 900°.
NSW	Anode	5.5	4.8	3.9	5.0	11,400	12,700	9,000	8,500

248	Tool	29.1	..	..	..	10,150	....	....	....
391	Cast iron	12.3	..	..	..	4,800	....	....	....

But little comment is necessary in this comparison. The effect of chemical purity of the material is indicated by the high quality of those materials of higher purity. The result of judicious annealing is shown in curves 389 and 390, a low-grade material markedly improved by the heat treatment.

Hysteresis tests on several of these materials are given below, all being carried to a uniform maximum flux density of B = 12,000 per square centimeter.

Bar.	Loop Area.	Relative Area.	H (Max.).
117A	8.65	1.	8.2
NSW	8.14	0.94	13.0
389	11.36	1.31	16.1
390	20.56	2.38	28.0
FB	7.25	0.84	10.3
AI	9.18	1.06	12.0

Bars 117A and NSW were tested after quenching, and this should be borne in mind in making comparisons.

A few general conclusions may be pointed out as a result of the tests.

The refining of commercial steels results in improvement of the magnetic qualities.

The amounts of impurities met with in commercial practice do not result in a serious deterioration of the quality.

Judicious heat and mechanical treatment has an importance equal to that of chemical composition, and proper annealing undoubtedly results in marked improvement in the magnetic quality.

Chemical Engineering Laboratories,
University of Wisconsin.

A Rotary Extractor for Precious Metals from Solutions.*

By W. D'Arcy Lloyd and Ernest T. Rand.

From time to time attempts have been made to precipitate gold and silver from their cyanide solutions while the precipitating agent was in motion, with more or less success. For example, zinc shavings have frequently been subjected to mechanical motion while in contact with the gold and silver cyanide solutions, and in most cases as far as actual precipitation of the precious metals was concerned, some success has been achieved, but mechanical difficulties have developed due to the method of applying motion by attrition, etc.

The main idea underlying all the attempts to perform the operation of precipitation with the precipitating agent in motion, is to avoid the fouling of the zinc, which is so painfully evident in the first compartments of all extractor boxes after a three days' run from time of dressing. It is well known that after thorough washing and redressing, the zinc will go on precipitating as briskly as ever until fouling starts again. The natural inference from this is that if the zinc could be kept continuously in motion, thus preventing fouling, the highest efficiency would be maintained. Having this in view, we have evolved the machine of which we endeavor to give some idea.

The precipitating agent used was zinc in the form of shavings and clippings, the latter being cut from sheet zinc and approximately ¼ in. to ⅝ in. square. The machine is a rotating one, with a water-tight casing of comparatively light steel plate, the casing being fitted with cross-sectional plates to divide it into compartments. In the machine with which the experiments were carried out, there were four of these compartments, but there is reason to think that the result required would be attained with three, the third being one-third larger than the first and second.

In the center of these division plates are securely fixed bearings, in which a hollow shaft rotates. Two circular disks, in each compartment distant from each other almost the full length of the compartment, are securely bolted to flanged collars, which in turn are fixed to the shaft. The shaft, with these discs and other attachments, form the rotor.

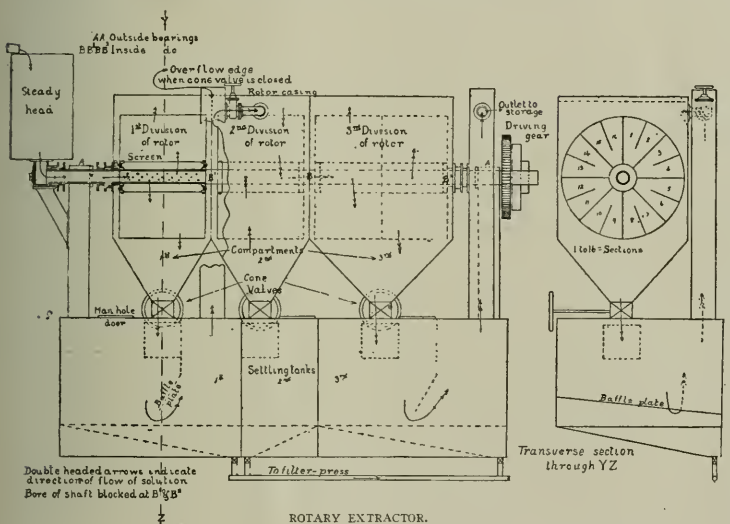
The rotor, besides being divided into compartments in length,

*A paper read before the Chemical, Metallurgical and Mining Society of South Africa. From the December, 1909, issue of the Journal of the Society. A short abstract of this paper appeared in our last issue, page 152.

is subdivided radially, in appearance much as a transverse section of an orange. There are sixteen radial divisions, which number was arrived at experimentally, the pressure of solution during rotation of a smaller number tending to press the zinc against the wall of the divisions, leaving a space between the zinc and the next wall. The use of the larger number of radial divisions obviated this tendency. These radial divisions are removable, and are lightly and strongly constructed of perforated (3/16-in. holes) steel plate.

Between and attached to the discs a suitable framework is fixed to contain the sections. There are many simple methods of retaining the sections when in position. Each section has a door of the same material as that of which the section is constructed, so that each is independent of its neighbor.

Around the shaft, and fixed securely to the flanged collars to which the rotor discs are fixed, is a strong screen of ⅛-in. mesh, leaving a space of about 2 in. between itself and the shaft, to prevent any fine material entering the shaft. The shaft is hollow, the bore being of ample size to allow of the free flow of the solution. The parts of the shaft enclosed by the flanged collars are perforated by inch holes to allow of the free egress and ingress of solution. At the required position the bore of the shaft is tightly closed to regulate the flow of the solution to wherever it is required.



ROTARY EXTRACTOR.

At the inlet end of the rotor for the solution is a small tank to act as a steady head, the top of this tank extending about 18 in. above the top of the rotor casing. At the outlet end of the casing, the pipe for carrying away the effluent is so placed that a constant level of the solution is maintained within the casing, which insures that the rotor will be completely submerged.

The bottom of each of the casing compartments is made in the form of a cone, and to this is fixed a valve which connects the cone with a settling tank, whose total capacity is equal to one and a half times that of the casing; this is divided into compartments to correspond with the number of those in the casing. All the solution passes from the casing into the settling tank from both the first and third compartments. The solution passes from the second compartment into the third compartment of the casing along the hollow shaft.

The compartments in the settling tanks have a sloping bottom to one point in each, at which point a valve and pipe connection is made communicating with one main pipe, which leads to a filter press. To the first compartment of the settling tank a stand-pipe of ample capacity is fixed, and stands outside and close to the rotor casing and projects a few inches above it. A pipe from this standpipe delivers into the second compartment of the rotor casing. A similar standpipe is supplied to the third compartment of the settling tank, and the outlet pipe from this delivers to the sump, the position of this pipe determining the level of the solution in the rotor casing, as before mentioned.

In the case of the first and third compartments of the settling tank a baffle plate is placed between the inlet of the rotor and casing and the exit to the standpipe. Each compartment is supplied with a manhole door. A screen basket is placed underneath each inlet to the tank to catch any fine zinc that may have passed through the rotor casing. A suitable gearing for rotating the machine is fixed to an extension of the shaft at the exit end of the machine, and about 1 hp is absorbed in a machine precipitating 250 tons a day.

The operation of the machine is as follows:

The solution enters the steady head, passes into the hollow shaft, and as the bore is blocked at the position corresponding to the end of the first division of the rotor, it passes out through the perforations, coming in contact with the zinc and leaving the rotor peripherically. The solution next passes into the settlement tank, and beneath the baffle plate, rising to the constant level in the standpipe to the second division. From here it again enters the perforated shaft, passing inwards through the zinc, along the shaft, and outwards through the zinc in the third section, again downwards, through the settlement tank (where the speed of the flow is greatly lessened by the size of this receptacle) beneath the baffle plate and up the standpipe, thence to the storage sumps.

By the arrangement of the settling tank it will be seen that there is but small chance of slimes being carried over to the other division. The rotor revolves from one to one and a half times per minute, and this is fast enough to allow of a slight motion of the zinc in their sections, which is as much as is desired.

All gold slime loosened from the zinc passes to the tank beneath; this can be removed at any time without stopping the machine, by closing the valve connecting the rotor casing and the settlement tank, and allowing the solution to overflow the division plate, forming the first and second compartments. The contents can then be pumped into a filter press, the solution from this being returned to any rotor desired. By means of the manhole before mentioned the inside of the tank can be washed out, this closed and valve slightly opened until settling tank is full of solution, then the valve opened full.

With reference to zinc consumption, it may be stated that the only zinc taken to acid was that which passed through the rotor in the form of shorts during its operation.

The following is a summary of the results obtained over a period of from November 4, 1908, to May 26, 1909.

Runs were made with strong, weak and slime solutions, respectively, the results obtained being as follows:

	Tons of solution per cubic foot of zinc per 24 hours	Value of solution entering, dwts.	Value of solution leaving, dwts.	Percentage of extraction Per cent.
Strong	1.01	2.221	0.053	97.6
Weak	1.84	0.383	0.029	92.3
Slimes	1.53	0.460	0.031	93.2

The above figures represent the mean of assay results over the individual runs.

At the clean-up the solution is shut off, the belt on step cone shifted to faster speed and rotor run on this for a few minutes, then stopped. (We might here mention that the sections on our experimental machine were fixtures, also there was no settlement tank below.) The sections on the top side were opened up, the zinc taken out and rinsed, though it was found that there was but a small quantity of loose slimes entangled. The zinc was returned and the section filled up with zinc from the second division. We found that finely cut filiform zinc broke up into shorts, when using strong solution, so that coarsely cut zinc would be preferable.

When coarse zinc or clippings are used, the adhering gold may be removed in an acid bath, as it was found in the case of clippings that 94 per cent of the gold was removed in a 5 per cent acid bath in 15 minutes, any deteriorating effect on the clippings being negligible. After the acid bath the zinc is thoroughly washed in clean water, the sections opened and examined, and fresh zinc added where necessary; it is found that the zinc in this form can be used in the rotor for a long time with a minimum consumption of both zinc and acid. To remove the gold from the zinc the sections are placed in a drum, which is revolved in the acid bath. We experimented for three weeks in our rotor with clippings and found the precipitation as good as under the conditions of the same space packed with filiform zinc (finely cut), the weight of clippings being 11 lb. to 1 lb. of shavings.

Our experimental machine was somewhat crude, and devoid of perhaps the greatest mechanical essential to its success, i. e., the settling tanks, the solution passing directly from one division to another without separation of precipitated slimes. The advantages of the rotor may be summed up as follows: (1) Ready access by authorized persons to the gold slimes, without stoppage of precipitation, enabling a daily clean-up to be made if required. (2) With clippings and coarsely cut filiform zinc, absence of breaking down and readiness of removal of adhering gold in an acid bath without consumption of all the zinc, with a consequent saving of zinc and acid. (3) Clean-up quick and cleanly with a consequent advantage of a minimum of loss. (4) Shortness of time rotor is out of action during dressing. (5) No fouling of zinc. (6) While in operation no danger of theft of gold slimes, as all valves would be locked.

In the discussion which followed the reading of the paper, the chairman, Dr. James Moir, remarked that on theoretical grounds, any rotary process will expose a larger surface of zinc, but, of course, it remains to be seen whether any particular device is successful commercially.

Mr. A. F. Crosse thought that there was "a great deal in this paper." The authors claim several advantages for their method, but they have left out one most important advantage, namely, the mechanical driving off of the hydrogen bubbles from the zinc; this removal of hydrogen helps precipitation.

Mr. E. T. Rand, one of the authors of the paper, confirmed that the bubbles of hydrogen on the surface of the solution are very evident indeed. There is a very violent action going on continually

The Chemical Industries of America.*

By Prof Charles E. Munroe

The topic which you have done me the honor to invite me to address you upon appears on first consideration quite specific, but investigation shows that this is not quite the case. Thus we find the popular idea of a chemical industry to be one producing acids, alkalies, salts, explosives, fertilizers, dyestuffs and extracts, pigments, distillation products and elementary substances like bromine, phosphorus, sodium and others, and the officials of the United States Census Bureau in 1880 in fixing a classification, styled in the various censuses "Chemical Production" or "Chemicals and Allied Products," adopted this popular view.

In discussing this, I have said,* "A reason for the variation in the industries included at the different censuses is found in the very general and indefinite title used, for in the strictest technical sense every material thing is a chemical, and accordingly every industry in which the materials used undergo a chemical change in the process of manufacture, as in the smelting of iron from its ores or the production of leather from a hide, may be considered as a chemical industry. It is evident that if this view of the significance of the title were taken "Chemicals and Allied Products" would properly cover every manufacture except those like furniture making, machine construction, or textiles, in which the material remains unchanged in composition during the manufacture, but is turned, or cast, or woven into other shapes. The popular idea of the term limits its application, but admits as chemical industries the manufacture of gunpowder, fertilizers, and similar mixtures, whose ingredients undergo no chemical change during the process of compounding the mixtures. It thus became necessary to decide arbitrarily upon the industries to be included. Those so included at the census of 1905 may be divided into the following classes. Sulphuric, nitric, mixed and other acids; sodas; potashes; alums; coal-tar products; cyanides; wood distillation; fertilizers; bleaching materials; chemicals produced by the aid of electricity; dyestuffs; tanning materials; paints and varnishes; explosives; plastics; essential oils; compressed and liquefied gases; fine chemicals; general chemicals."

These were consequently divided into 19 different classes which were given separate treatment. The combined statistics for these classes for the censuses of 1900 and 1905 are set forth in the following table, the statistics of these two censuses only being compared because they alone dealt with the same materials.

TABLE I—CHEMICALS AND ALLIED PRODUCTS OF UNITED STATES 1900 AND 1905

	Establishments, Number	Wage Earners, Number	Total Wages	Materials Used, Cost	Products, Value
1905	1,786	59,198	$29,515,863	$176,400,680	$282,469,216
1900	1,691	46,700	21,783,335	124,018,044	202,506,076
Increase	95	12,498	7,732,528	52,382,636	79,663,140
Per cent. of increase	5.6	26.8	35.5	42.2	39.3

From Table I it is observed that there was an increase in every item enumerated, but that not only was the actual increase in the number of establishments less than that of any other item, as was to be expected, but that the percentage increase was less. This indicates that the growth of these industries was rather by increased production of existing establishments than by the creation of new ones. In fact, in a more detailed analysis it was found that in some industries the number of establishments had actually decreased, though each of the other items, as enumerated in Table I, showed an increase.

The greater percentage increase in wages over that of the percentage increase in wage earners shows that the lot of the latter was improved and possibly indicates that a better class of labor was employed, and, since the percentage increase in the number of salaried officials for these establishments was 29.6, while the percentage increase in salaries was but 32.4, it is obvious that the wage earners fared, on the whole, better than the salaried officials.

A wholesome feature to be observed is that while the increase in the number of men employed was 12,104, the increase in the number of women employed was but 413, while there was a decrease of over 10 per cent in the number of children employed. I speak of this condition as a wholesome one, because, outside of the clerical and perhaps analytical work, the duties to be performed in these establishments is essentially man's work

* Address delivered, by invitation, on Dec. 9, 1909 at the annual meeting of the American Institute of Chemical Engineers in Philadelphia

* Bull. 92—Census of 1905, page 9, by Charles E. Munroe.

The greater percentage increase in the cost of materials used as compared with the percentage increase in the value of the products shows the growing necessity of intelligent and careful management and skillful workmanship to prevent waste and to increase yields. This is emphasized by examination of the additional item of miscellaneous expenses, which, while less in the total than any of the values given in Table I, showed an increase of 77.2 per cent.

As indicated, the census classification of "Chemicals and Allied Products," which gave the data just discussed, is a purely empirical one, and it deals with but a very few of the true chemical manufactures of the United States. It is not possible to derive from the returns, of the various industries as taken, the data for an exact scientific classification, such as has been referred to above. Yet, in order to arrive at a better conception of the application of chemistry in manufacturing industries and its magnitude, we may follow such a scheme of classification as that employed in many chemical technologies, though here again we meet with the difficulties common to classification and we are compelled to include in our data some of the products of purely physical processes, either because these processes are operated collaterally with, or are related to, the predominating chemical processes, or else because the products are closely associated with the chemical products.

In assembling this data it should be said that in order to compare the data of the different epochs one must first eliminate from the data of 1900 the returns for neighboring industries, for the census of 1905 was a factory census which considered only the results of manufacture as carried out in factories, and not solely for consumption at the point where manufactured, as is generally the case with neighborhood industries. The results of this treatment are set forth in Table II.

TABLE II—CHEMICAL INDUSTRIES OF THE UNITED STATES 1880 TO 1905

	1905	1900	1890	1880
Establishments, number	56,580	53,567	40,451	34,864
Wage earners, avge. number	1,107,714	943,166	677,123	490,776
Wages, total	$575,635,257	$438,404,062	$305,884,278	$176,227,726
Materials used, cost	2,933,660,817	2,215,162,767	1,247,239,582	924,573,773
Products, value	4,716,490,371	3,628,641,475	2,152,490,514	1,357,593,293

Table II, imperfect though it be, both in the industries it includes and those it omits, gives a better conception of the actual magnitude of the industries in which chemical transformations play a part, and which are, therefore, really chemical industries, than Table I does and in so doing it shows the value of the products for 1905 alone to be nearly seventeen-fold greater than is set forth in Table I.

The increase is easily accounted for by noting that items, such as soap, with a product valued at over $68,000,000; glass over $79,000,000; illuminating gas over $125,000,000; dairy products over $168,000,000; refined petroleum over $175,000,000; paper and wood pulp over $188,000,000; bread and other bakery products over $269,000,000; sugar and molasses over $277,000,000; vinous, malt and distilled liquors over $340,000,000; smelting and refining of copper, lead and zinc over $461,000,000; iron and steel over $905,000,000, and many other items have been added to those embraced in Table I.

The simple enumeration of these items indicates how incomplete the statistics usually presented as those of the chemical industries are and how insufficient the popular conception of the chemical industries is. Yet even the data of Table II does not present the case in full, since all agricultural products, amounting in value in 1900 to $4,717,069,973, are really the results of chemical processes and are, therefore, the products of chemical industries, although not factory products.

As with Table I, so with Table II, the deductions are more readily drawn by observation of the increase and percentages of increase for each item at the various epochs. These have, therefore, been ascertained and are set forth in Table III.

Considering now the data of Table II, and more particularly the increases and percentages of increase set forth for each epoch in Table III, while keeping firmly in mind the fact that we are here dealing with two 10-year periods and one five-year period, it is again to be noted that both the actual and percentage increases in the number of establishments are the smallest of all the various increases set forth, and that increase for this item for the 1900-1905 period is not actually less than for 1890-1900 and 1880-1890, as should be expected, but is proportionately less, thus emphasizing what has been deduced from Table I as to the increased production of existing establishments.

TABLE III—INCREASES AND PERCENTAGES OF INCREASES FOR CHEMICAL INDUSTRIES

	1900 to 1905		1890 to 1900		1880 to 1890	
	Increase	Per Cent.	Increase	Per Cent.	Increase	Per Cent.
Establishments, number	3,013	5.6	13,116	32.4	5,587	16.0
Wage earners, average number	164,548	17.4	266,043	39.3	186,347	38.0
Wages	$137,231,195	31.3	$133,519,784	43.3	$129,656,552	73.6
Materials used, cost	718,498,053	32.4	967,923,182	77.7	322,665,809	34.9
Products, value	1,087,848,896	30.0	1,476,150,961	68.6	795,987,221	58.6

Likewise the consideration of the data for this larger number of industries extending over a greater length of time shows that not only is the percentage increase in wages nearly as great at the census of 1905 as those for cost of materials and greater than the value of products, but that, while the proportionate increase in the number of wage earners for the 1900-1905 period is less than that of 1890-1900, the proportionate gain in wages is greater. In fact, all statistics point to markedly improved conditions for the wage earner in the chemical industries, and to his increased participation in the income from the enterprise. This fact is one to be reckoned on by the chemical engineer in making up his estimate for the cost of a projected enterprise, which it is proposed to install.

The statistics of Tables II and III, on the other hand, do not so markedly support the deductions drawn from Table I as to the increase in cost of materials used when compared with the increase in the value of the products in 1900-1905. However, when we consider the larger items included in these later statistics, such as iron and steel; smelting and refining of copper, lead and zinc, and others, we may each of us recall a variety of labor-saving devices which have been invented and introduced for cheapening the cost of production and handling of the raw materials of these industries, and that the inventions have increased in number and perfection with the growth in magnitude of these industries.

An increase in cost of materials is in conformity with the long-recognized natural law of supply and demand. A modification of this law through which labor may get its fair share of increase and capital may get its fair share of increase, while the actual cost may not proportionately be increased, has been brought about in recent times through the increase in the magnitude of the unit of demand, or, in other terms, the quantity handled. As stated, this has to an extent been rendered possible by the introduction of labor-saving machinery, much of which has been invented in this country.

But, in my opinion, and if I read aright the reports of foreign commentators on our chemical industries, in their opinions, the chief modification in the operation of this law has been made

in this country through the development of "team work," though the writers style it organization or systemization.

Entering on my fortieth consecutive year of college teaching I might, from what has been so persistently dinned into my ears, have been led to believe that "team work" originated in the minds of the college youths who flocked to Franklin Field or to the Harvard Stadium. Sitting on the bleachers with practical politicians and presidents, I might be led to suppose that "team work" was an invention of the professional athlete. As a fact, the idea of "team work" is a very old one and military in its essence and original application. It is embodied in our national motto. It is commemorated in the "Charge of the Light Brigade." But this older practice, while greatly promoting efficiency, demanded such unreasoning subordination that the private soldier was properly looked upon as but "food for powder," and when this system was introduced into the factory the operator became but "a cog in the machine."

The modification in this plan of "team work" which has been developed to such advantage in the industrial plants of this country has come through a recognition of the great value of individuality and the necessity for its preservation and development, and it has been demonstrated that the higher the intelligence of the individuals who merge their entities with that of their fellows in a common purpose, and the more complete their comprehension of the means used and the end sought, the more successful is the result, whether gauged by the quality, or the quantity, or the cost of the output. I am happy to say that the chemist has destroyed the older military idea, even in the army, for by his invention of high-powered smokeless powder he has compelled armies to fight in open order so that each individual must exercise his own powers in attack and defense, and be trained to take the initiative in case of necessity.

Naturally the application of labor-saving machinery and of "team work" is most readily made and yields most efficient results in the production, transportation and handling of the raw materials of our larger industries, and it is in these that we find the smaller proportionate increase in the cost of materials

American industries, in which the chemical industries are included, have signalized themselves by the introduction of standards, by the introduction of interchangeable parts into mechanisms, by the wide application of labor-saving machinery, and by the use of "team work." Yet notwithstanding the vast resources of this country, their ease of access, and the cheapening, by methods such as described, of many of costs of production, the cost of "living," not only here, but throughout the civilized world, has steadily increased, and I attribute this largely to the work of the chemist.

At St. Louis, in 1904, I said: "Technical chemistry, then, invades the domains of economics, of politics, and of diplomacy. A striking example of its effects in economics and politics is found in the settlement of the silver question. Gold is a most widely diffused metal. It has, for instance, been shown by assayers at the United States Mint at Philadelphia that if the gold in the clay of the bricks of which the buildings of the Quaker City are built could be brought to the surface, the fronts would all be gilded. In the past our processes for the isolation of this metal have been so costly that only the richer ores would bear treatment. Large bodies of low-grade ores which have been discovered and mountains of tailings carrying values were looked upon as worthless, while enormous quantities of copper, lead, and other metals containing gold were sent into the market to be devoted to common uses, because the cost of separation was greater than the value of the separated products. Eight years ago, when the "silver question" was made the national issue, while the orators were declaiming from the stump, the chemists were quietly working at the problem in their laboratories and factories. Manhe's process for bessemerizing copper ores was combined with the electrolytic refining of the product, so that even traces of gold were economically recovered, while the cyanide processes, such as the MacArthur-Forrest, the Siemens-Halske, the Pelatan-Clerici, and others for the extraction and recovery of gold from low-grade ores and tailings, were successfully worked out and put into practical operation to such effect that by the cyanide processes alone gold to the value of $7,917,129 was recovered in the United States in 1902, which is more than was ever won throughout the whole world by all methods in any one year up to 1661, and probably up to 1701. The data for other purposes is not at hand for 1902, but the returns for 1900 show that gold to the value of $88,985,218 was recovered in the treatment of lead and copper ores in the United States, of which $56,566,971 worth was recovered in refining. It has but recently been publicly proclaimed in this city of St. Louis that the "silver question" is settled, and it is settled, but it was settled largely through the efforts of the technical chemist and metallurgist."

With the improvements in methods and diminution in cost of extraction the Pactolean stream has continued to flow in steadily increasing volume* until the flood of gold has become so great that its purchasing power has become markedly reduced, and costs, measured in terms of gold, have become markedly greater. With this condition well determined the chemist has again stepped in to increase the cost of living by requiring the application of costly methods of inspection of food, drugs, and other articles of consumption; by demanding the elimination of preservatives which permitted the abundance of the harvest being kept until time of need; or the plethora of one locality being sent to the land smitten with leanness; by insisting on the introduction of expensive sanitary arrangements. Pure-food laws are the vogue and all the other needs of man are becoming the subject of special legislation, some wise, but much otherwise. It would prove an interesting exhibit if a statistician were to assemble the actual costs in the administration and execution of these laws in this country alone during the past five years.

I speak with earnestness because I have repeatedly been a participant in these movements, and am even now engaged in an analogous humanitarian enterprise, and I know that a certain result of all such endeavors to improve the lot of man is to put the community to an increased expense.

(To be concluded.)

The Precipitating Effects of Substances Containing Various Forms of Carbon and Cellulose on Cyanide Solutions Containing Gold and Silver.**

By A. J. Clark and W. J. Sharwood.

These notes contain the results of a series of experiments and observations made by the authors at the Homestake Mine, Lead, South Dakota, together with other information on the subject, gathered from various sources.

Relative Activity of Some Precipitants.—Two sets of experiments were made on the precipitating effect of gold-bearing solutions of various precipitating substances, with the results tabulated below under Series A and Series B. In each experiment 300 c.c. of solution were taken. In Series A five grams of the precipitant were added; the mixture was stirred vigorously for a moment and then filtered, with further agitation

*The Production of Gold from 1878 to 1908 Was as Follows

Year	World's Production		Production in United States	
	Fine Ounces	Value	Fine Ounces	Value
1878	5,761,114	$119,092,800	2,476,800	$51,200,000
1888	5,330,775	110,196,900	1,604,841	33,175,000
1898	11,827,866	256,879,700	3,118,398	64,461,000
1908	21,378,481	441,912,300	4,854,140	94,560,000

** A paper read before the Chemical, Metallurgical and Mining Society of South Africa. The complete paper, as printed in the January issue of the *Journal* of the Society, contains a list of references to existing literature.

each time the funnel was refilled with the liquid. After filtration the filtrate was passed through the filter again, and thus exposed to the sediment retained by the filter a second time.

In Series B the conditions were the same as in Series A except that a larger quantity of precipitant (which was not weighed, but was at least 20 grams) was taken, and there was only a single passage through the filter.

Series.	Precipitant.	Original assay of solution.	Assay of filtrate.	Percentage of gold precipitated.
A.	Graphite (Dixon's flake).....	$2.63	$2.65	0
	Bituminous coal (40 mesh)...	"	2.45	7.0
	Coke (40 mesh).....	"	2.11	19.6
	Charcoal, pine (40 mesh)....	"	1.92	27.0
	Calcium carbide.....	"	2.50	5.0
	Zinc dust	"	.02	99.3
B.	Graphite	2.73	2.73	0
	Coal	"	2.13	22.0

Repeated tests have shown similar results. Pure graphite, whatever its source, seems to be entirely without effect on the gold in cyanide solutions, and anthracite coal nearly so. The semi-bituminous or sub-bituminous coals of Western United States (practically bituminous coals, but having the high water content and brownish tinge when powdered, characteristic of lignites) have a feeble precipitating action; well-burned coke is fairly effective and charcoal much more so. Lubricants containing graphite with mineral oil, intended for use in rock drills, and the clean graphite extracted from them, are entirely without effect after several hours' contact with solution.

Either a sufficiently long contact with, or a slow percolation through a relatively large amount of bituminous coal, removed as much, in some cases, as 99 per cent of the gold in a cyanide solution, but the efficiency of the coal as a precipitant fell off with repeated use, as is the case with charcoal.

Effect of Wood Ashes Containing a Small Proportion of Charcoal on the Cyanide Extraction of Gold from Tailings Containing Pyrites.—These experiments were made in percolators upon pyritous tailings, to which various proportions of ashes were added, together with a suitable amount of lime (about 5 lb. per ton), the charges being thoroughly mixed. The cyanide solution was in actual contact with the charges four days, but the charges were drained dry once during their treatment, as well as at the conclusion.

The tailings assayed about $1.75 in gold per ton, and upon them, under normal conditions, without the presence of wood ashes, an extraction of at least from 70 to 75 per cent would have been obtained.

The results of the experiments were as follows:

Percentage of ashes added to tailings.	Percentage of gold extracted by cyanide.
0.17	52.8
0.8	46.0
1.73	35.8
8.0	3.5

At the Homestake cyanide plants, when similar ashes or charcoal have been inadvertently introduced into the treatment vats, a very small percentage has been found to lower the gold extraction from between 70 and 75 per cent to below 60 per cent. As to the origin of these ashes, in one case it had been traced to an old stope, into which they had been dumped from the surface some years before; in another case charcoal had been produced by the charring of the timbers in a former mine fire, and had become mixed with the ore treated. Sometimes charcoal and cinders have been introduced into plants by the dumping into the mill launder of ashes from a heating stove, as a convenient means of disposal; at other times accumulations of ashes and clinker, produced by the burning of chips (collected from the mortars), had been run through the batteries.

Some years ago heavy losses were reported in the cyaniding of ore at an Australian mine, at which crushing and amalgamation were facilitated by the device of heating the ore by burning it like limestone in a furnace with alternate layers of cordwood, and quenching the heated ore with water. A similar kiln treatment has been used successfully at some small California mines, rendering refractory ore containing pyrite and tellurides more amenable, both to crushing and amalgamation in an arraster, but it seems to have proved fatal to cyaniding in the former instance, probably owing to the presence of charcoal. Park (in "The Cyanide Process," 1897, ed.), states that in New Zealand it was found advisable to hand-pick the charcoal from dried ore prior to crushing and cyaniding.

Several instances have been reported where "graphite" ore (usually slate or schist) has caused precipitation. Most likely this is due to the fact that the carbon in such carbonaceous schists is often far from being completely converted into graphite, and may exist largely in the form of hydrocarbons, in a condition similar to that of partially burned coal or wood.

Precipitating Effect of Chips, Charcoal, etc., Upon Gold- and Silver-Bearing Solutions.—Some floating rubbish, consisting of charcoal and charred pieces of wood, as well as some clean chips and twigs (which came from a settling dam and creek bed) and particles of coke (which came from the smokestacks of the locomotive and steam shovel) were skimmed from the surface of the cyanide solution in a slime agitator vat.

The solution contained approximately:

Gold, 0.023 oz. per ton ($0.47).

Silver, 0.28 oz. per ton ($0.14).

Potassium cyanide, 0.025 per cent.

The skimmed rubbish was rinsed twice with water, and dried at 100°C. It was then divided into two portions, one containing the charcoal and charred wood, and the other the clean chips and twigs. The two portions were then weighed, some of each being burned in clean roasting dishes in a muffle. The substances were assayed, before and after burning, with the following results:

No.	Material.	Proportion of total weight of original sample.	Ounces per ton. Gold.	Ounces per ton. Silver.	Values per ton. Gold.	Values per ton. Silver.	Total.
1.	Coke and charcoal charred wood	40%	2.25	7.50	$45.27	$3.75	$49.02
2.	Ash of same....	¼ (or 25% of total ash)..	18.00	60.00	365.40	30.00	395.40
3.	Clean chips and twigs.....	total ash)...	0.96	10.8	10.48	5.40	24.88
4.	Ash of same....	¼ (or 75% of total ash)..	0.96	10.80	19.48	5.40	24.88

As neither of the two classes of material carried more than its own weight of solution, when removed from the vat, obviously a considerable precipitation had occurred in proportion to the weight of the material, the coke, charcoal, etc., precipitating the gold contents of approximately 100 times their weight of solution, and the twigs, etc., precipitating ten times their weight, the corresponding amounts for silver contents being 27 and 10, respectively.

In reply to a suggestion by Mr. Caldecott that these chips, etc., might have been partially burned or charred, it may be stated that they were to all appearance unaltered. It is possible, however, that some of them had lain in the dam or creek for months, or years, so that decay may have commenced.

Decaying Wood.—That decaying wood is an active precipitant for gold in cyanide solution was evident from a series of samples taken from a residue dam, the sand discharged into which contained appreciable amounts of solution as well as traces of dissolved gold, so that the aeration consequent on discharging no doubt resulted in the dissolution of a little more gold. While the average assay value of the sand was lower than that of the residue as discharged, the lower strata were slightly higher in gold contents, as might be expected from the leaching that had since taken place. At two points, however, a decided concentration of values was noted; one of these was found to be in the neighborhood of a pine post, and another around the decaying stump of a tree that had been killed by the residues. Mr. Caldecott's suggestion that the effect of the wood fibre itself is practically nil, and that apparent precipitation by wood is due merely to absorption of solution, is confirmed by our next series of determinations.

Absorption of Gold and Silver by Cellulose.—Several writers have published experimental results showing a large decomposition of cyanide and also a considerable precipitation of precious metals, due to contact with wood, canvas, cocoanut matting and other fabrics used as filters—all forms of cellulose. Some of the writers, working on a laboratory scale, had failed to take into account the ratio of the surface of the precipitating material they used to the volume of solution experimented upon, and did not then compare this ratio with that which would have resulted by working on a large scale. Consequently some operators have been misled with believing that discrepancies were attributable to precipitation by the wood of tanks or filter bottoms, and therefore to hope that, at some future date, the burning of the material would reimburse them for their supposed losses.

As the writers referred to differed considerably from one another, either as regards their opinions, or in experimental results, we give some of our results obtained by examination of various materials that had been exposed to gold-and-silver-bearing solutions for considerable periods.

(1) **Materials from a Sand Leaching Tank.** This was nearly 40 ft. in diameter, the bottom having an area of 1200 ft. It had been in use over a year when the first tests were made. The values given represent the contents of the entire material in the tank, through which many thousands of tons of solution had circulated, carrying up to $6 per ton in gold, and up to $2 silver.

(a) Bottom Filter Cloth of Canvas.—8-oz. duck, 1,200 sq. ft. in use for eight months. Entire cloth: gold, 5 cents, silver 2 cents.

(b) Bottom Filter of Cocoanut Matting.—1200 sq. ft. in use 12 months. Entire filter: gold, 46 cents; silver, 3 cents.

(c) Wooden Slats.—These supported the filter and were of unpainted Oregon pine, 3800 running feet with a cross-section of 2.5 x 1.5 inches, about quarter of the material being crozed out; altogether about 75 cu. ft. In use 12 months. Entire material: gold, $16.60; silver, $5.90. Wood per cu. ft. gold, 22 cents, silver 8 cents.

(d) Fine Slime.—This had accumulated under and between the filters during eight months, and consisted of fine ore, together with precipitated carbonate of lime; altogether, 200 dry pounds. Entire material: gold, 20 cents; silver, 4 cents.

In the last case, and probably in all, most, if not all of the values were contained in solution absorbed and not necessarily precipitated.

(2) **Tank Staves.**—(a) The staves of a similar large leaching tank, after use between three and four years with sand averaging $3 gold and $1 silver value per ton. They were of California redwood, originally painted inside with two coats of P and B. paint, and outside with red oxide of iron in linseed oil. A slight coating of carbonate of lime had formed on the inside. A large sample from these staves, burned and assayed, yielded only traces of gold and silver.

(b) Similar staves from a leaching tank in use at another plant for four years contained 40 per cent moisture. The dried wood contained gold, 47 cents per ton; silver, 3 cents per ton.

(3) **Precipitating Box.**—A precipitating box of 1½-in. lumber was painted inside and out with P and B. paint, and used three years to precipitate low grade cyanide solution with zinc shavings, the slimes averaging about $1 to $5 per lb. Samples were taken by boring completely through the wood at various points in sides and bottom, and were burned and assayed. A little zinc slime was visible on the surface.

The average value of the material, including a trace of adhering precipitate was: Sides, 0.75 cent per sq. ft. bottom, 2 cents per sq. ft.

(4) **Mine Timber.**—A piece of blackened but sound timber (yellow pine) which had been some time underground, and contained ferrous and ferric sulphates derived from mine water was tested. At the time of the test it contained 56 per cent of water. Kept in contact with about three times its weight of cyanide solution, which assayed $1.20 per ton gold value, no precipitation took place in 20 hours. It seems evident, therefore, that wood, when well painted with any suitable protective medium, absorbs little more than traces of precious metal from cyanide solutions of ordinary value.* As dry pine and redwood absorb about their own weight of water, one would expect such wood, if dried after a thorough soaking in solution to assay the same value per ton as the solution taken up—evaporation and precipitation excluded. Alternate soaking and drying or evaporation on the outside of unpainted wooden launders or tanks in a dry climate, might be expected to result in a distinctly higher value in the wood. Adhesion of rich telluride slime or floured amalgam may also cause an increased value.

It is difficult, however, to reconcile with one another the results obtained by the following authors, and only those of Bosqui are at all in line with our own experiments. The other writers named worked entirely on a laboratory scale.

S. H. Williams (*Eng. and Min. Jour.*, Sept. 9, 1905, p. 80, 435) found that an 8-in. wooden launder, 75 ft. long, used seven months at a cyanide plant in New Mexico, having passed 63,000 tons of solution, worth $3 per ton, contained: 2.766 oz. gold and 32.646 oz. silver in 15.5 cub. ft., or 0.18 oz. gold and 2.1 oz. silver per cub. ft., or a total value of about $4.65 per cu. ft. An apparent typographical error in the original article makes the value $60.45 per cu. ft.

A. N. Mackay (*Trans. Inst. Min. Met.*, 1905, p. 14-41; *Min. and Scient. Press*, June 17, 1905, p. 90-387) states that red pine, from a tank used 18 months, in which had been treated only 1200 tons of ore containing 20 dwt. of gold per ton, yielded 1.24 oz. gold per ton of wood.

F. L. Bosqui (*Eng. and Min. Jour.*, Feb. 26, 1898, p. 65-248) experimented with pine and redwood dressed and rough, both with intermittent exposure and drying, and with continuous immersion, for periods up to 12 months, using solution which averaged $5 gold per ton and more or less silver. The highest absorption was with rough pine, exposed altogether about 12 months, this assaying $5.18 gold and 14 cents silver per ton of wood.

On the whole, it seems probable that the precipitative effect of charcoal may be occluded gases, but definite proof is lacking. S. Brussow (*Zeit. Chem. Ind.*, Kolloide, 1909, p. 5-137; *Jour. Chem. Ind.*, Oct. 15, 1909) in a recent article, attributed the precipitation of gold from haloid salts by charcoal to absorption. This seems most unlikely, as he admits that the chlorine of gold chloride remained "almost entirely" in the solution; and we have found that charcoal, which has been in contact with solutions of either chloride or double cyanide of gold, is thoroughly impregnated with metallic gold easily distinguishable with a good lens or low power microscope.

*When launders of unpainted wood are used in the Plattner chlorination process they absorb gold enough to make it worth while to burn them to recover it. The same is true of canvas used for concentration in mills where floured amalgam escapes the plates or where the tailings contain fine gold or rich tellurides. Absorption of silver similarly takes place in hyposulphite leaching. This is preventable by soaking the launders, etc., in paraffin or painting with asphaltum.

On the Determination of the Atomic Weight of a Chemical Valence and on the Mean Chemical Energy Per Unit of the Atomic Weight.

By Dr. Gustavus Hinrichs.

The Weight of a Valence.—After reading the paper in the March issue, it will be readily understood why the ratio *H* to *O* did not come out exactly equal to 1 to 16, but gave for *O* 16 values for *H* slightly in excess of unity. It is this excess that foreshadowed the separate existence of the chemically active portion of the hydrogen atom.

Supposing the slight excess to be due to the hydrogen alone

and due to the smallest weight of matter imaginable (a pantogen atom), we have found the atomic weight of pantogen (the primitive ponderable matter) equal to 1.128 of our unity, as already referred to in the preceding paper.

But this view of valence cannot be restricted to one chemical element, to hydrogen, which, on account of its small atomic weight, would reveal it first; it must be a general property for all elements. We should, therefore, have two such prominent panatoms on oxygen, three on nitrogen, four on carbon.

Calling the weight of this panatom-valence v and retaining the absolute values for the nullovalent mass of the element-atoms we shall have, for example, the entire atomic weight of silver nitrate $170 + 10\,v$.

Hence the atomic ratio of silver nitrate to silver, which for $v = O$ is $R = 1.57407$, will become $R' = R\,(1 + 0.050\,v)$.

This method of calculation is general and now will have to be applied to all cases. Let us see whether we can get a determination for the value of a valence from the existing syntheses of silver nitrate, made so carefully by Berzelius, Stas and Richards. We must, however, remember that the values of Stas are affected by systematic errors which do not show in the work of Richards, because he has used nearly the same weights of silver in all his determinations. For this reason it will be impossible to take the value calculated for v from this synthesis as entirely exact.

The analytical ratio according to the determinations of Stas is 1.57473; according to Richards 1.57479. The atomic ratio for $v = O$ is 1.57407, giving enormous excess of 66 to 72, which has remained a good deal of a puzzle for a long time. We have made various attempts to get at the real reason of this enormous excess without satisfaction beyond the point that the fact stated by Schützenberger fully accounts for the systematic error of Stas and for his two values, the one for dried, the other for fused nitrate.

The above relation gives

$$R' - R = 0.00072 = 0.050\,Rv = 0.079\,v,$$

from which we get $v = 0.009$ to nearest thousandth of a unit.

The synthesis of water by Noyes gives the same value as can easily be verified. It is true these two series of determinations belong to the best we have, but it will not do to accept them as final and *absolutely exact* in this matter, which is close to the limit of precision of analytical work.

From the investigations I have been able to complete I am sure that the value v of nine-thousandths of a unit is *a higher limit*, and that the true value is less than this amount.

It will now be necessary to apply this method to all the 300 reactions used during the past century for atomic weight determinations. For $v = O$ this work has been completed; the results have been put into five such tables as the first, published last July in this journal. The results have been discussed for two of these tables in a recent article in the *Moniteur Scientifique*, and the general results have been represented by diagram and table in connection with my Quelques Letters, page 39, just from the press.

There can remain no doubt but the absolute atomic weights are true as a first and a very close approximation. But it will now be necessary to repeat the reduction of this entire mass of data, the product of laboratory work of a hundred years, for a convenient assumed value of the weight of a valence. From the results of this work the true value of v can then be readily estimated.

This second approximation—which will probably be the final one—we have already carried out in a number of the most important determinations, using the value $v = 0.005$ as the most convenient and practical.

The following more formal statement of the present condition of this great problem may be useful:

I.—The principal part of the atom of any chemically active element is not chemically active, but nullovalent.

II.—The weight of this nullovalent part is strictly commensurable, generally to the unit, not unfrequently to the half, rarely to the quarter, and still more rarely to the eighth of a unit of our scale.

III.—The active part of the valence consists of as many panatoms prominently placed at one end of the prismatic or discoid nullovalent mass as the valence. True At. Wghts., pages 222-223.

IV.—The higher limit of the weight of the unit valence is 0.009; its true value may be 0.005 only, and will have to be determined by a second, final revision of the laboratory work done during the past century.

V.—The atoms of the argonoids or nullovalent elements have a definite geometrical form without polar or prominent panatoms.

Energy of Chemical Reactions.—The combination of 2 gram atoms of hydrogen with 1 gram atom of oxygen sets free an energy equal to 68 kg calories, in round numbers.

The combustion of 1 gram of hydrogen thus produces 34 kg calories.

There is no other element or substance known which by combustion produces as high an amount of caloric energy.

We cease to wonder at this exceptional position of hydrogen when we consider that in a hydrogen atom the chemically active accelerative force is weighed down by the smallest inert atomic mass, namely, of one unit only.

By following this trend of examination for the most prominent oxygen and chlorine compounds, we shall find the caloric energy per unit of mass quite regularly and rapidly diminishes with the increase of the nullovalent mass, as it ought to do, if our above deduction is correct.

The following two tables show that this remarkable diminution of the chemical caloration with the increase of nullovalent matter of the atoms is indeed a fact.

TABLE I.—FOR AO.—Hinrichs' Principles Chem., 1874, p. 148.

Formula.	Caloration in Kgr. Degrees C. For Compound.	For One O.	Weight A.	Per Unit Weight of A.
H_2O	68	68	34	34.0
CO_2	96	48	6	8.0
CO	30	30	12	2.5
SO_2	71	35.5	16	2.22
P_2O_5	381	76	12.4	1.63
P_2O_3	97	32	21	1.52
As_2O_5	222	44.4	30	1.48
ZnO	85	85	65.5	1.30
FeO	69	69	56	1.23
SnO_2	138	69	59	1.17
As_2O_3	154	51	50	1.02
CuO	44	44	63.5	0.69
PbO	55	55	207	0.26
Ag_2O	12	12	216	0.06

TABLE II.—FOR ACl.—Hinrichs' Principles Chem., 1874, p. 148.

Formula.	Caloration in Kgr. Degrees C. For Compound.	For One Cl.	Weight A.	Per Unit Weight of A.
HCl	24	24	1	24
$NaCl$	95	95	23	4.13
$KaCl$	101	101	39	2.59
$FeCl_2$	99	49.5	28	1.76
$ZnCl_2$	101	50.5	32.7	1.55
$SbCl_3$	86	29	40	1.38
$AsCl_3$	75	25	25	1.00
$CuCl_2$	59	29.5	32	0.92
$PbCl_2$	90	45	103.5	0.43
$AgCl$	35	35	108	0.32

This may be sufficient for a preliminary statement of the general mechanism of chemical activity.

St. Louis, Mo., March 12, 1910.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our Special Correspondent.)

Grading of Pig Iron.

Important Proceedings.

In consequence of the resolution passed at the last autumn Congress of the International Testing Association at Copenhagen, that for the purpose of defining the quality of pig iron more accurately than was possible by the present method of grading by fracture appearance, the committee having the matter in hand should inquire in the various countries concerned as to how far specifications by analysis could be usefully substituted for grading by fracture, a meeting of representatives

of bodies interested in the iron and steel industries was held at the Iron and Steel Institute on Feb. 10 under the presidency of Mr. J. E. Stead, who represented the Iron and Steel Institute and the Cleveland Institution of Engineers.

Mr P. Donaldson, on behalf of the Scotch Pig Iron Trade Association, wrote expressing his opinion that grading by analysis was the correct method to adopt; but, as yet, he questioned if the departure from the grading by fracture would be accepted in Great Britain.

Mr. H. Pilkington (British Foundrymen's Association) wrote pointing out the different conditions existing in England and in America, where practically all the foundry pig was made from hematite. The value of the fracture method of grading had been proved, yet it was somewhat crude when numbers alone were used for classification. An improved method was desirable, because fracture, by itself, was not a reliable index of definite properties. All the suggested chemical specifications were open to objection, and their authors did not always appreciate the commercial aspect of the situation. At present the only practicable course was to keep to grading by fracture numbers and sell on the silicon content.

Mr. J. E. Stead then rose, and after referring to the great difference between conditions of trade in England and those in America or Germany, said fracture appearance had sufficed for many years for large export sales. Grading by analysis only would considerably enhance the cost of pig iron, and it would be better that the change should be gradual, as, in fact, it was coming about now, especially in some consignments to America and Germany. British makers did not object to selling by analysis, but the cost would increase, and at present sales by analysis were not applicable to the trade generally. Another question for consideration was the storing of surplus pig, and he believed that ironmasters, warrant-holders and storekeepers would oppose the change on account of the increased expense and the inconvenience it involved. He objected to any change from the existing practice.

Mr. T. C. Hutchinson (Cleveland Ironmasters' Association) said the system of grading by fracture appearance had proved its efficiency for a period of over 60 years, and fracture appearance did to some extent indicate the analysis. In iron from Cleveland ore the phosphorus, manganese and carbon were practically uniform, and the variation in silicon and sulphur was shown by fracture sufficiently for every practical purpose. In the case of large sales of iron intended for steel making, sale by analysis was desirable and would doubtless become more customary, but for general trade purposes the existing grading met every requirement. He quite agreed with Mr. Stead's observations as to storing by analysis. Cleveland iron was bought in big lots by large firms who sold it in small quantities, and in shipping such large cargoes it would not be practicable to keep small analyzed parcels separate. He was sure that makers, merchants and buyers would all object to the proposed change; and, on behalf of the association which he represented, he had to state that its members would refuse to be bound by any resolution to grade their iron by analysis which might be passed by the meeting.

Mr. H. J. Skelton (British Iron Trade Association) believed that the agitation for the proposed change began in the United States in consequence of difficulties which arose when sandless pig was first produced there. It was well known that almost every parcel of pig made in this country was analyzed. If pig iron were to be sold by analysis a difficulty would generally arise in fixing limits of variation. He dealt largely with special pig, of which analyses were always given regardless of its destination, but the analysis was not guaranteed, in order to provide against possible rejection on account of small variations. Although analysis was becoming more customary, it was not possible for British makers to agree to invariable sale by analysis.

Mr J. E. Stead remarked that the agitation was not coincident with the advent of sandless iron in America. Foundrymen learned the value of making their mixtures in accordance with analyses, and for that reason were now adopting the practice of buying by analysis.

Mr. W. F. Foster (Staffordshire Iron & Steel Institute) said the information as to composition to be obtained by fracture had not yet been completely worked out. The comparison of fracture with analysis would give more knowledge than a superficial observer would credit. Fracture revealed comparatively small differences in phosphorus content.

Mr. W. H. Butlin (British Iron Trade Association) stated that there was an overwhelming majority of the members of the association he represented in favor of the retention of grading by fracture. Those in favor of fracture grading represented an annual output of 1,476,000 tons and those against it only 120,000 tons. Purchase by analysis was progressing in this country. It was certainly beneficial in the case of foundry pig, and might lead to the use of cheaper iron for certain purposes, and this scientific mixing might bring about economy in manufacture.

Mr. J. E. Stead mentioned that purchasers were protected by legal decisions which established certain limits to permissible variations in analysis.

Mr. H. J. Skelton remarked that British pig iron was superior to the product of other countries. Even in Germany, with scientific control, the use of British pig iron was indispensable because the native pig did not yield the desired results.

After some discussion as to the wording of the resolution to to be put to the meeting, Mr. T. C. Hutchinson said he agreed with Mr. Foster that the extent of the information given by fracture appearance was not yet appreciated. Selection by analysis alone was impossible, and fracture appearance gave a very good indication of the composition of the iron.

Mr. G. H. Roberts (Royal Arsenal) proposed: "That the conditions governing the sale of pig iron in Great Britain make it undesirable to recommend any immediate change in the existing practice of grading, whether by fracture or by analysis."

This was seconded by Mr. W. H. Butlin, and carried unanimously.

The resolution will be communicated to the International Testing Association by Mr. G. C. Lloyd, member of the council for Great Britain.

Properties of Alloys of Copper, Aluminium and Manganese.

At the meeting of the Institution of Mechanical Engineers on Feb. 18 the discussion on the ninth report to the Alloys Research Committee (abstracted on page 154 of our March issue) was resumed by Dr. Glazebrook, who said that the results of the high-temperature tensile tests agreed closely with earlier observations and demonstrated that a considerable increase in temperature did not diminish the strength of the alloys, but had a tendency to augment it. With regard to abrasion tests three of the alloys exhibited much less loss than rail steel and tool steel. As to corrosion the degree to which some of the alloys were affected was but slight, and those alloys appeared to be really valuable.

Mr. Sherard Cowper-Coles said that electro-deposited metals might have quite as high a tensile strength as smelted and rolled metals. The study of cold electro-deposited metals and alloys would assist in clearing up several obscure points in metallurgy. Lantern projections of photomicrographs were employed to demonstrate the speaker's contentions. One showed electro-deposited copper in crystals at right angles to the cathode surface, which corresponded to the surface of the ingot mold in casting. Another was a section of a copper strip deposited in a fine V-shaped spiral cut in a mandril. If the groove were rounded instead of angular the arrangement of the crystals would be radial, and weak cleavage lines would occur. A third slide exhibited the setting of the crystals and how the deposited copper was removed in a continuous strip. The effect of particles of impurities was then shown with crystals radiating from a minute nucleus. Such structure might account for the breaking up of metals during rolling. Cast metals might

contain small particles of foreign matters which would similarly cause radial crystallization and weak cleavage lines. The effect of variation in the rate of rotation of the anode was demonstrated by the deposit of copper on a cone. The tensile strength of the copper taken from near the base of the cone was 24 tons per square inch, while the copper near the apex of the cone gave only a few tons. It was conclusively established that metals having all the various physical properties of cast, drawn or rolled metals could be produced by deposition without any heat treatment, rolling or drawing.

Mr. H. F. Donaldson doubted the utility of some of the alloys reported on because of their cost. Equally good tensile strength could be obtained with much cheaper ingredients. He would compare the alloy No. 2 of the author with one containing 36 per cent of zinc, 55 per cent of copper, 2 of iron, 4 of manganese, and 3 of aluminium, having a tensile strength of 47 tons and 30 per cent elongation, which cost but £10 per ton as against £17 per ton for the "No. 2" alloy. He questioned if manganese was the best material to add, and thought nickel might give better results. He had brought a tool made from an alloy consisting of 90 per cent of copper and 10 per cent of aluminium, hardened by hammering. It was used in a cordite factory, and retained its sharpness for fully 48 hours. The speaker produced some bronze knives, used in cordite works, which had thin blades with very sharp edges.

Mr. H. L. Heathcote said he had experimented during the last two years with light aluminium alloys, with the object of producing a non-corroding alloy for cycle rims. He found that pure aluminium corroded far less than an alloy containing 3 per cent to 4 per cent of copper when acted on by solution of sea salt and moist air at 60° C. Alloys of aluminium with 1 per cent to 5 per cent copper, of aluminium with 1 per cent to 9 per cent of iron, of aluminium and nickel, and of aluminium, copper and zinc, all corroded more than commercial aluminium. The only alloy which satisfactorily resisted corrosion was one containing 1.4 per cent of manganese, which when rolled to 15-gage flat strips had a tensile strength of 12 tons, 12 per cent to 15 per cent elongation, and 0.45 per cent to 0.55 per cent contraction. He preferred tensile strength to weighing for measuring the extent of corrosion.

Dr. Rosenhain, in the course of his reply, with reference to Mr. E. F. Law's remarks on the use of a temperature of about 1000° C. and a silicon content for alloys Nos. 10 and 11 of 0.57 per cent and 0.25 per cent, said the heating certainly affected the silicon content, which was always about 0.2 per cent or 0.3 per cent, but the temperature quoted was necessary for the addition of the manganese. He did not think anybody could much improve on his results.

The Boiling Points of Metals.

A paper by Mr. H. C. Greenwood on the "Influence of Pressure on the Boiling Points of Metal" was recently read before the Royal Society. Previously work at reduced pressures had been limited by lack of material capable of maintaining a vacuum at high temperatures, and for similar reasons nothing had been done on the effect of high positive pressures. These difficulties had been avoided by arranging the whole furnace inside an enclosure, in which the desired changes of pressure could be produced. Heating was effected electrically; the temperatures were observed optically, and the boiling point determinations were made by a visual method. Experimental pressures ranged from 100 mm of mercury to 50 atmospheres. The boiling point of bismuth under 102 mm of mercury was found to be 100° C., and under 16.5 atmospheres 2060° C. The boiling points

Market Prices in February, 1910.

Copper was in the neighborhood of £60 15 0 when the month opened, but fell away during the first week to £58; thence recovered uncertainly to £59 12 0, at about which price it has remained.

Tin, after a fall to £145 15 0 on the 4th, rose to £150 15 0 during the next 10 days, and has maintained the price of £151 up to time of writing.

English Lead has been rather depressed, falling steadily from £13 to £12 10 0, afterward recovering up to £13 10 0.

Iron.—Cleveland dropped from £2 10 10 to £2 10 0, afterward recovering to £2 11 2.

Scotch Pig down from £2 16 10 to £2 16 3, following the same movements as Cleveland, closing at £2 11 2.

Hematite dropped from £3 3 10 to £3 3 0, afterward recovering to £3 4 5.

Synopsis of Metallurgical and Chemical Literature.

Smelter Fumes.

The Elimination of Smelter Fume has been a serious and important problem with Western copper and lead smelters. Permanent injunctions against their operation were obtained by the farmers of Salt Lake City, Utah, and it became necessary either to abandon the works or to evolve a scheme for the elimination of sulphuric and arsenious acids from the fume discharged into the air. How well the chemists and engineers of the United States Smelting Company have solved the problem is shown by L. A. Palmer in an article in the March, 1910, issue of *Mines and Minerals*. Not only have the courts permitted the renewed operation of the entire plant treating both copper and lead ores, but the company is recovering a valuable by-product in the arsenic which is refined and marketed. All of the fumes from blast and roasting furnaces, amounting to 350,000 cu. ft. per minute are suitably neutralized and bagged. The bagging of blast-furnace fumes, which carry the sulphur as SO_2, has long been practiced, but no attempt has hitherto been made to bag roaster fumes carrying SO_3. Pot roasters are used for sulphide ores, and reverberatory roasters for blast-furnace matte. The fume from the pot roasters is conducted through a flue to a certain point, adjacent to which is a brick furnace which is fired with slack coal over a layer of lime rock, and to which a small amount of zinc concentrates is added. The fume from this brick furnace passes into the flue mentioned and mingles with the fume from the pot roasters. The zinc oxide generated thus neutralizes the SO_3 in the roaster fume forming zinc sulphate, which is subsequently settled and bagged. The fume from the reverberatories is cooled during its progress through flues leading from the furnaces, and at a suitable point their SO_3 content is neutralized by the introduction of crushed lime into the flue. The bag house ultimately receives all fume and the gases discharged from its stacks are practically colorless and invisible. The bag house is of the usual type, and the bags are shaken by a device operated outside the building. The

dust from the roaster section is returned to the roasters, while the blast-furnace dust is sent to the arsenic plant after it has spontaneously ignited and burned to a loose sinter.

The arsenic plant consists of two Brunton arsenic furnaces and a refining furnace. Clean coke fires are the source of heat in each. The arsenic is volatilized as As_2O_3, and the lead sinters and is resmelted. The arsenic fume from the Brunton furnaces is settled in a long chamber, provided with baffle walls. It is withdrawn at intervals and sent to the refining furnace, which is of the reverberatory type. The settling chambers for this furnace are of the same type and design as for the Brunton furnaces. The product is crystalline and is ground to make a commercial product. The daily output is about two tons of refined arsenic assaying 99.87 per cent pure As_2O_3. Operators at the arsenic plant are compelled to wear a suitable change of clothing and to take a bath before going off shift.

Copper.

The Sampling of Anode Copper with particular reference to the silver content has been made the subject of an investigation at the Washoe Smelter, Anaconda, Mont., and the very interesting results are presented in the March, 1910, *Bulletin Amer. Inst. Min. Eng.* by William Wraith. A disagreement between smelter and refinery led to the investigation. The smelter method of sampling consists in "shotting" the molten stream of copper into water, by "batting" the stream at intervals with a wooden paddle. The shot is then dried, cleaned and screened through a 10-mesh screen of No. 8 wire to remove fines, the oversize being further screened through a 4-mesh screen of No. 20 wire to remove the coarse shot. The undersize of the last screen is taken as the sample. The method used at the refinery is one developed by Dr. Edward Keller, of Perth Amboy, N. J., in which every fourth anode of each lot is drilled, using a 99-hole template. The holes of the template are used in continuous order from 1 to 99, one hole to each anode, regardless of the lot being sampled. For example, if one lot required the drilling of only 90 holes, the next lot would commence with hole 91. These drillings for each lot are ground to pass a 16-mesh screen, the sample being later mixed and quartered. Finally, the quarter selected is screened through a 40-mesh screen, the oversize and undersize being weighed, and the ratio of coarse to fine being carried out in weighing up the assay ton for analysis. Still another method investigated was the "ladle-shot" method, in which a ladleful of copper is shotted by pouring the molten stream over a wooden paddle into water. Samples taken by these various methods were carefully assayed for comparison and to determine the possibility of segregation of the silver in (1) different parts of the flowing stream, (2) the cast anodes, (3) successive portions of a ladleful, and (4) in the "skulls" formed in the ladles due to the solidifying of a shell of copper.

In the smelter shotting method it was proved that there is reasonable uniformity of the charge during the pour, and that different portions of the stream give uniform silver assays. The use of a wooden paddle or of a hot clay paddle seemed to make no difference. In the refinery drilling method it was found that six anodes selected at regular intervals during the casting of a lot, each drilled in 99 places by the template, gave almost uniform assays. Methods of comparing assays from a random anode with those of the lot from which it came were also tried and gave concordant results. A table is given showing the very fair concordance of the shotting and drilling methods when carefully carried out. The investigation of the ladle method showed it to be the least satisfactory due to the segregation of silver toward that portion of the metal solidifying last. The ladle-shot samples gave considerably higher silver results than the furnace shot samples. The "skulls" were impoverished in silver. Successive samples poured from the same ladleful showed a regular increase in silver content from first to last with the "skull" much lower in silver. Under these conditions each of the ladle samples was higher in silver than the smelter shot sample. A ladleful allowed to cool completely showed a remarkable segregation in the top of the button. The conclusions reached are that the shot sample taken from the furnace stream, and the drilling sample taken according to Dr. Keller's template, will check and give the true silver content of copper; and that the ladle-shot method gives higher results due to a segregation of silver toward the portion last solidifying.

The Behavior of Copper Slags in the Electric Furnace has been investigated by Lewis T. Wright, who presents the tabulated results in a paper published in the March, 1910, *Bulletin Amer. Inst. Min. Eng.* Ferruginous copper slags treated in the electric furnace will yield metallic iron. The author has shown that the iron recovered will contain practically all of the copper, gold and silver and more than 50 per cent of the sulphur of the original slag. The buttons are hard and clean, but not brittle. The conditions of the experiments were as follows: Slag used, 700 grams to 900 grams; strength of current 70 amp to 80 amp; time of fusing 1 hour to 1 hour and 20 minutes; weight of metallic button obtained, 153 grams to 218 grams; percentage concentration, 22 per cent to 31 per cent. The slags used carried from 0.25 per cent to 0.55 per cent Cu; 0.18 oz. to 0.33 oz. Ag per ton and from $0.15 to $0.40 Au per ton. The buttons obtained carried from 0.82 per cent to 1.62 per cent Cu; 0.48 oz. to 1.4 oz. Ag per ton; $0.40 to $1.20 Au per ton, and 88 per cent to 94 per cent Fe. The slag resulting from the fusion carried from a trace to 0.1 per cent Cu; trace of 0.025 oz. Ag per ton; trace, Au and 5 per cent to 19 per cent Fe.

Tin.

Flotation Process for the Concentration of Tin Ores.—The Elmore oil flotation process, which we described in its latest development in our Vol. 6, page 187 (May, 1908), has recently found a new application to the concentration of tin ore. This is described in the article by E. S. Elmore, of the *Mining Journal*, of Aug. 28, 1909. There is an old tin mine in Dolcoath, Cornwall, where for many years past those parts of the workings have been abandoned which contain mixtures of the ordinary tin oxide (cassiterite) with sulphides of various metals, such as copper, zinc, iron and arsenic. Such mixed ores were valueless, because if concentrated on water-dressing appliances, the sulphides, or, at any rate, a large proportion of them, were collected with the tin oxide, and the resulting product was too impure for the tin smelter. For the past two years an Elmore vacuum plant has been in operation there with complete success. The complex ore, after crushing, is treated in the vacuum machine, with the result that practically all the sulphides are removed as a concentrate which is almost free from tin, and substantially all the tin is left in the tailings from the Elmore machine, these tailings being passed on to usual water-concentrating appliances for the recovery of the tin, which is found in practice to be practically free from sulphides. Some of the Dolcoath tin ores are free from impurities except copper sulphide. From this ore the vacuum process produces a high-grade copper concentrate, in some cases as high as 10 per cent of copper, which is readily salable to the copper smelter.

Following the success at Dolcoath the process is about to be applied to two other widely separated parts of the world viz., the Straits Settlements and South Africa. With the tin concentrates from South Africa a working trial of the Elmore process on about 35 tons of this material has recently been carried out, the results being given below:

	S %	Cu %	As %	Sn %
The impure tin concentrate treated assayed	1.69	0.26	2.91	72.38
The sulphide product assayed	20.57	2.78	33.0	3.64
The cleaned tin product assayed	0.12	0.03	0.14	74.0

The loss of tin in the sulphur product amounts to only 6 lbs. per ton of material treated, while 95 per cent of the total impurities have been removed.

Zinc.

Flotation of Zinc Ores.—Broken Hill ores have presented some of the most difficult problems in ore dressing and, as a result, a number of processes have had their origin in that district. Donald Clark, director of the School of Mines, N. S. W., describes in the *Eng. and Min. Jour.* for Feb. 26, 1910, a combination roasting and flotation process devised by E. J. Horwood for the treatment of some very finely divided and intermixed sulphides of iron, lead and zinc. The process depends upon the fact that when a mixture of these sulphides is roasted the iron and lead are converted into oxide and sulphate at a low temperature, from 300° C. to 400° C., while the zinc sulphide is unaltered. This partly roasted mixture is then subjected to a heated-acid oil-flotation process, whereupon the zinc sulphide floats and can be collected, while the gangue with the iron and lead will sink. With suitable mechanical equipment in the way of roasters, tanks, spitzkasten, etc., an initial product carrying 32.4 per cent Zn and 22.3 per cent Pb was made to yield a zinc concentrate carrying 50.8 per cent Zn and 0.3 per cent Pb, and a lead concentrate carrying 49 per cent Pb and 2.6 Zn.

Gold and Silver.

Cyanidation of Silver Ores.—The application of cyanidation to silver ores is most largely practiced in Mexico, where the system employed is generally well known. In striking contrast to the usual method is the treatment used at the Zambona mine in the Alamos district of Sonora. As described in the Feb. 26 issue of the *Min. and Sci. Press* by B. B. Kniffen, the unusual feature is in the extreme rapidity of the solution of part of the silver, and the peculiar advantage of concentrating the ore prior to cyaniding. The ore is an orthoclase felspar, brecciated and filled with calcite. The mineral is argentite, distributed throughout the gangue in all sizes down to minute particles. This mineral is easily concentrated on tables, so that 50 per cent of the silver content of the ore can be removed in this way. The tailing is then cyanided. A solution carrying 0.075 per cent free KCN is mixed with the ore in the ratio of 6:1, the pulp being treated in Dorr classifiers. The sand goes to tube mills, the discharge from which is returned to the classifiers which in turn discharge their overflow to Dorr slime thickeners The underflow is stored for delivery to filter presses as needed. In this manner the silver is extracted from the ore by merely concentrating and grinding in solution without agitation of any kind. The silver is reduced from 16 ounces to 1.3 ounces per ton.

As illustrating the sensibility of the ore to cyanide treatment the following table is given showing the reduced silver content at various stages of the treatment:

	SILVER, OZS.
Ore after concentration	8.30
After mixing with solution	4.48
Tube mill heads	5.52
Tube mill tailing	5.28
Discharge from Dorr thickener	2.72
After standing 6 hours	2.28
After a 6-hour agitation	2.18
After a 9-hour agitation	1.96
After an 18-hour agitation	1.82

For a short time the mill was operated without concentration and by cyanidation only. It was found necessary to use a solution carrying 0.15 per cent free KCN and to supplement the other treatment by a 30-hour treatment in Pachuca tanks.

Dredging Beach Sands.—An ingenious manner of overcoming the difficulties encountered in handling Nome beach sands is described in the March issue of *Mines and Minerals*. The richest portion of the beach could not be reached in the ordinary manner, as it was under tidewater. It could not be dredged in the ordinary manner, for sand and water would fill the excavation as fast as made and thus prevent reaching bed rock. Mr. E. L. Michot conceived the idea of a barge carrying a caisson which could be lowered to bed rock and through which small areas could be worked consecutively. As carried out the construction is about as follows: The barge is 75 ft. x 32 ft. over all. Through its center, longitudinally, is a well 50 ft. x 10 ft. Along each side of the well is a track carrying a head-frame mounted on trucks. The head-frame supports the caisson, which is of sheet iron and air-tight, and measures 10 ft. long, 10 ft. wide and 7 ft. high in its working chamber. The caisson is raised and lowered over the head frame by means of a hoisting engine suitably located at one end of the barge. A centrifugal pump connected with the caisson raises the sand to the deck of the barge where it is treated in a long sluice box. Pressure is maintained in the caisson equal to the outer pressure of sand and water, so that the centrifugal pump may more efficiently clean the bed rock. Gravel worth upward from $2 per cubic yard is being worked.

Chemical Engineering.

Decomposition of Soda in Steam Boilers.—It is not generally known that the ordinary soda which remains in boiler water from the softening process is apt to dissociate in the boiler and to render the water acid, owing to the generation of free carbonic acid. Lime and soda are added to water, to precipitate carbonates of calcium and of magnesium, and, further, magnesia hydrate, and in order to secure this object, a slight excess of soda has to be used. The excess must be sufficient, and yet as small as possible. This soda accumulates to a certain extent in the boiler, even when the boiler is blown off, and it is this soda which is decomposed. A case of this nature was brought before the Mannheim Branch of the Verein Deutscher Ingenieure last November. The firm of Messrs. C. F. Böhringer & Söhne, of Waldhof, noticed that their distilled water, obtained by the condensation of boiler steam, was acid. This acidity—it was not overlooked—disappeared in the course of time, and was correctly ascribed to carbonic acid. It was at first thought that some bicarbonate had found access to the boiler, in which it would be decomposed. The softener was, therefore, overhauled. When the trouble was repeated, it was suspected that the temperature in the water softener, 80° C., might not be sufficiently high to decompose all the bicarbonate; the temperature was hence raised to 100° C., boiling point, but the carbonic acid still appeared in the boiler water. After having been informed of these observations, Dr. Grünewald ascertained that Basch had proved some time ago that boiler water contained the soda, not all as carbonate, but largely as caustic soda, and that carbonic acid was given off in the boiler. Now, the presence of carbonic acid undoubtedly favors the rusting of iron, though it is not indispensable for starting the oxidation of iron in the presence of water, and this point, while not important, deserves some attention, because caustic alkali is regarded as preventing the formation of rust. (Lond. *Engineering*, March 11.)

White Lead.—By an act of the French Parliament, which took effect July 20, 1909, the manufacture and use of white lead for either interior or exterior painting and decorating is to be prohibited after five years from the date of the act. London *Engineering*, of Jan. 14, observes that this is the result of agitation started some years ago by the French Socialists, who made the most extravagant claims regarding the ill effects of white lead on the painters, causing a high death rate from lead poisoning. The bill against the manufacture and use of white lead was introduced in the Lower Chamber and was passed. The Senate sought to amend the act by providing indemnity for the manufacturers who were thus to be deprived of their business, but the Lower Chamber would not accept the amendment. The Minister of Labor was also against the amendment, thus establishing as a principle the right of Parliament to destroy private property without compensation. The entire procedure is against industrial progress. By observing suitable precautionary measures, the manufacture and use of white lead are no more dangerous than many other industries. In fact, there is said to be more lead poisoning among employees of accumulator and storage-battery works than among

painters, but no provision is made for the protection of the health of these men. The French law has evidently been passed wholly as a measure alleged to be in the interest of labor, and without regard to industrial progress and property rights. Engineers have already begun to seek for a suitable substitute for white lead as a pigment. Some experiments already carried out indicate that nothing will take its place satisfactorily and that zinc white is not at all adapted to certain uses where lead was formerly employed.

Specific Heat and Chemical Equilibrium of Ammonia Gas.—An interesting apparatus for determining the specific heat of gases is described by Prof. Walter Nernst in *Zeit. f. Elektrochemie*, Feb. 1. He used this for determining the specific heat of ammonia gas, which is of special interest for the calculation of the NH_3 equilibrium. For the molecular heat of ammonia he finds the following formula to hold true up to 700° C.:

$$C_p = 8.62 + 0.0020\,t + 7.2 \times 10^{-9}\,t^3$$

For the formation heat of ammonia he finds at 850° C.

$$Q = 30{,}220$$

and states that it should be correct within 1500 calories. On the basis of his new determinations he finds that the application of his new thermodynamical theorem to the ammonia equilibrium gives results better in agreement with the facts than when older and less accurate figures were used.

Gas-Washing Bottles.—A recent Faraday Society paper of Dr. N. T. M. Wilsmore (read Jan. 10) describes gas-washing bottles with a very slight resistance to the passage of a gas. Three forms are described. In one, a short side tube is joined to the inlet tube of an ordinary washing bottle and bent upward so that the gas bubbles passing through it carry some liquid with them, causing constant circulation of same. In a second and more efficient form, the gas passes through a length of 5-mm tubing, slightly inclined to the horizontal. Below this, and connected to its ends, is a bulb of liquid, so that here again the passage of gas through the tube causes a circulation of liquid. The third form described is a modification of the Richardson wash-bottle, in which the pressure is reduced by lengthening the nozzle through which the gas enters the washing bulb. (From advance sheets.)

Storage of Coal.—The results of an investigation into the deterioration of stored coal, now being carried on by the Technologic Branch of the United States Geological Survey, are given by H. C. Porter and F. K. Ovitz in the March, 1910, *Jour. Ind. and Eng. Chem.* Coal absorbs oxygen from the air during storage without forming CO_2 and the amount of oxygen absorbed accords approximately with the deterioration in heat value. Oxidation may be largely prevented by immersion in water. Methane is evolved from freshly mined coal in quantities of importance as bearing on mine explosions, but of no importance as a loss of fuel value. Outdoor tests are being conducted to determine the extent of the loss during storage in the open as compared with immersion under water. Laboratory tests are being carried on to determine changes in the yields of gas, tar, and ammonia, through deterioration in storage.

Enameling Cast Iron for industrial uses is discussed in a general way by Harold Holcroft in the *Jour. Soc. Chem. Ind.*, for Feb. 15, 1910. The object of enameling, the testing of enameled articles, the preparation and requirements of various enamels, and the principles of their application are the heads under which the subject is presented.

Electrochemistry.

Electrode Losses in Electric Furnaces.—In an appendix to his paper on electrode losses, just published in Vol. XVI of the *Transactions* of the American Electrochemical Society, Mr. Carl Hering gives briefly the results of his tests of carbon and graphite between 100° C. (cold electrode end temperature) and 900° C. (furnace temperature). Higher furnace temperatures had not yet been used in the tests. In general, the curves have but a slight slope at the highest temperature of the test (about 900°) and all appeared to tend toward becoming nearly horizontal. Hence the error would probably not be great to use these values even for somewhat higher temperatures until the actual determinations for these temperatures have been made. This would surely be far more correct than to use the older data. Reduced to a terminal temperature of 100° C. the values for about 900° C. furnace heat are as follows in the inch units specified in Mr. Hering's article in the October issue of our last volume (Vol. VII, page 442): Graphite $r = 0.000323$; $k = 0.740$. Carbon $r = 0.00148$; $k = 0.329$. They are presumably accurate to within a few per cent, and were determined from a number of readings taken with considerable care. For graphite, the electrical resistivity falls nearly rectilinearly from about 0.000330 at 390°, hence only slightly, the curve being nearly horizontal. The thermal conductivity falls faster, also nearly rectilinearly, being about 0.861 at 390°, but it seems also to tend to approach the horizontal. For carbon the electrical resistivity falls faster, from about 0.00166 at 360°; the curve is slightly concave upward and tends to become horizontal. The thermal conductivity rises quite fast from about 0.226 at 360° and also tends rapidly to the horizontal, being concave downward. The much-discussed ratio of the heat conductivities of graphite and carbon, therefore, turns out to be only about 2 to 1 instead of 8 to 1, 10 to 1 and 18 to 1 as have been claimed by others. This, at least, is the case for 900° C. furnace heat, and applies to the mean values under operating electrode conditions, and to properly proportioned electrodes.

According to these constants for 900°, the so-called "electrode voltage," for 1°, for graphite is 0.0447 and for carbon 0.0639. This means that the minimum loss for carbon is about 50 per cent greater than for graphite, and not slightly less, as has been thought before. On the other hand, the difference in cross-sections between carbons and graphites, for the same furnace and electrode length, is less than that determined from the older approximate figures, the carbons being now only 3.21 times as large as the graphites. There is another matter of interest brought out by these tests. The mean electrical resistivity (under electrode conditions) falls more rapidly for carbon than for graphite. This means that an appreciably larger half of the heat due to electrical resistance will be generated in the colder half of the electrode, hence nearer the terminal. This heat will, therefore, have a shorter path for escape to the terminal than if the heat were generated more evenly throughout, as with graphite. In other words, a carbon electrode, it seems, would be hotter a short distance from the cold terminal than one of graphite would. This, of course, is an unfavorable feature and may account in part for the increased minimum loss for carbon. It seems to explain why the "mean" thermal conductivity turns out to be so unexpectedly high.

Quite recently two interesting papers have appeared in the *Proceedings* of the Am. Inst. Elec. Eng. of March. One is a paper by Mr. Carl Hering on "the proportioning of electrodes for furnaces" (giving the results of his tests in numerous tables and diagrams), the other is a mathematical paper by Dr A. E. Kennelly "on the modifications in Hering's laws of furnace electrodes introduced by including variations in electric and thermal resistivity." Both will be abstracted in our next issue.

Composition of Electro-Deposited Alloys.—A recent Faraday Society paper of S. Field (presented Jan. 18) discusses the conditions which determine the composition of electro-deposited alloys. Continuing the study of the quantitative composition of electro-deposited alloys, those of copper and silver have been examined. For the electrolyte, a mixture of the double cyanides was again used. Ordinarily silver is more negative than copper, but the difference in their character is such as would not seem to indicate any difficulty in depositing them simultaneously from a cyanide solution. The composition

of the deposits was obtained by dissolving in nitric acid, and estimating the silver as chloride, except where the copper was obviously small, when that metal was determined. When a copper coulometer is in circuit the ratio (R) of the weights of alloy and copper deposited in the coulometer gives a figure from which, under ideal conditions, the composition of the alloy may be determined thus:

$$\text{Percentage of silver} = \frac{241}{R}(R-2)$$

Experiments soon proved that simultaneous deposition only occurs within very narrow limits. Thus when the metals in the solution are in the proportion of even 1 equivalent silver to 34 equivalents of copper no deposition of copper occurs under ordinary conditions of current density, but when in the proportion of 1 equivalent silver to 100 equivalent copper, simultaneous deposition proceeds more readily. To examine the effect of such varying conditions as current density, free cyanide, and temperature, the following conditions were necessary:

1. Large volume of solution, and, therefore, little change of composition during each experiment.

2. Constant addition of silver to maintain a uniform content of that metal.

3. Solution containing not more than 0.4 grain silver per litre.

Under such conditions it was found that the percentage of the more positive copper varies as follows:

1. Percentage of copper increases with C.D.

2. Percentage of copper decreases with rise of temperature of solution.

3. Percentage of copper decreases with additions of free cyanide.

Thus the results follow the usual course as previously shown for brass, and the two metals become more widely separated in the presence of potassium cyanide. In no case were the deposits of any value physically, except where the silver very largely predominated. (From advance sheets.)

Rapid Electrodeposition of Metals.—A recent Faraday Society paper (read Jan. 10) of Dr. F. Mollwo Perkin and Mr. W. E. Hughes described a rotating cathode employed for rapid electrodeposition of metals. It consists of sheet platinum spun up so as to form a narrow thimble, the upper end being open and having a stout iridium wire fused to it. This electrode, which has an active surface of 16.3 cm, is rapidly rotated within a cylindrical platinum gauze anode. In other cases, particularly when graded potential methods are employed, a spiral anode of platinum is rotated within the gauze cylinder, which then functions as cathode. In the potential measurements a cylindrical glass funnel with a glass tube sealed in the side is employed for holding the electrode.

Dr. Henry J. S. Sand pointed out that the form of electrode ultimately found most suitable by the authors very nearly approached the one used by him, and if the investigation had been extended to this a further improvement would have been found. He considered the authors' electrodes were inferior in smallness of resistance to the electrolyte, stirring efficiency, and ease of manipulation. His electrodes, again, could be used with ordinary beakers and far less wash water was required. He had discarded the use of NH_4NO_3 solution as a connecting liquid, as on one occasion the auxiliary electrode gave completely wrong results. Dr. F. M. Perkin, in reply, said the electrodes described in the paper were simpler and less costly than Dr. Sand's. He preferred the tap-funnels to beakers, and found no difficulty in raising the temperature of the electrolyte before pouring into funnel. (From advance sheets.)

Electrochemistry of Organic Compounds.—A very useful summary of recent progress made in organic electrochemistry based on papers printed between May, 1907, to September, 1909, is given by Prof. K. Elbs in *Zeit. f. Elektrochemie*, Feb. 15. The article deals with the electrolysis of organic compounds and electrochemical reductions.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Treatment of Iron Before Tinning or Galvanizing.—Tinned plates are frequently imperfect by reason of the presence of minute uncovered areas, perforations, or so-called "pinholes," in the coating metal, such imperfections being highly detrimental by reason of the tendency of the coated metal to become corroded or pitted at these points or areas. While all surfaces of iron or steel which have been thoroughly cleaned and freed from grease or oxide are very susceptible to oxidation or corrosion, such imperfections are particularly liable to occur in plates which have been subjected to an acid pickling process, and their presence may in this case be partly or wholly attributed to the persistence in metal to be coated of acid conditions arising from the baths employed for the removal of the scale. According to a method patented by Mr. Henry Howard, of Boston, Mass., the iron or steel articles are first freed from scale by the usual methods, as by immersion for a suitable time in an acid pickling bath. The articles are then immersed, preferably after a brief washing or rinsing with water or a suitable alkaline solution, in an alkaline electrolyte, being connected therein as the cathode. As electrolytes, solutions containing a carbonate or hydroxide of an alkali are must suitable. Since the sheets under treatment are the cathodes, caustic soda is formed at them and hydrogen evolved. By this procedure the cleaned surfaces are rendered far less liable to corrosion, any residual acid conditions are quickly eliminated and the metal may immediately receive a coating of tin or zinc by immersion in the molten metal in the usual way. (949,575, Feb. 15, 1910.)

Utilizing Steel Scrap.—Steel scrap, rich in silicon, etc., is usually treated by melting it in a furnace in which its silicon or other alloy content is burned away and goes into the slag and becomes a waste product. Mr. J. P. Woods Beckman, of Parnassus, Pa., takes the scrap containing silicon or other alloy content and heats it in a closed furnace whose temperature is below the temperature required to fuse the scrap in such a manner as to prevent any substantial oxidation, bringing the scrap up to a white heat. He then adds to the scrap molten steel which has been melted in a separate furnace, and thus utilizes the excess heat of this steel to melt the scrap, which has been preheated to a point slightly below its melting point. In this manner he is able to utilize practically all of the alloy content of the scrap without loss and at a very slight additional cost. (947,031, Jan. 18, 1910.)

Electrolytic Iron.—Electrolytic iron is produced from ores by the following process of Mr. Alexander S. Ramage, of Newark, N. J. (the patent being assigned to the Electro Steel Company of Canada, at Welland, Ont.). Magnetite containing titanium is heated in a rotary cylinder in presence of water-gas with an excess of hydrogen at a temperature below the melting point of iron until the iron content is reduced to a metallic sponge. The reduction of the iron occurs at a dull red heat, whereas the titanium oxide is unaffected by this treatment. The iron powder, or sponge, containing unreduced titanium oxide, but substantially free from carbon, is discharged into air-tight vessels, where it is cooled, and is then electrolytically refined in an electrolyte containing ferrous sulphate and ammonium sulphate, together with some organic material, such as glycerin or glue. The cathodes are sheets of iron or revolving tubes. The current density is 10 amp per square foot and the temperature 140° Fahr. The cathodes are heated to expel the occluded hydrogen. The titanium oxide passes into the anode sludge in the electrolytic vats. (949,004, Feb. 15, 1910.)

Gold and Silver.

Filtering Device.—Continuous filtration of slimes is the subject of a patent granted to George Ridgway, of Kalgoorlie, Western Australia, who has perfected a mechanical appliance for the purpose mentioned. The process is continuous, but is

quite different from any of the half dozen or more continuous slime processes recently devised. The inventor retains the "basket" type of filter, and alternately lowers and raises the baskets into exhaust, washing and discharge vats in his machine. The construction will be apparent by reference to Figs. 1 and 2. The annular trough is divided into sections *A*, *D*, *E* and *F*. The first is filled with the pulp to be filtered, the second with water or wash solution, the third devoted to drying and pumping, and the fourth to the discharge of the cake. The various sections are divided by suitable partitions over which the baskets are raised and lowered in their continuous path around the entire tank. The filter frames are made of iron pipe bent into a V-shape and covered with a suitable filtering medium. All of the frames in a basket are properly connected. On each set of filters is a device for engaging a track at certain intervals around the tank, whereby they are lowered and raised at the proper time. Agitators keep the pulp in a homogeneous condition during filtration. When the machine is started all of the filters in tank *A* are in connection with the vacuum apparatus and a cake of slime is formed on the filter, while the

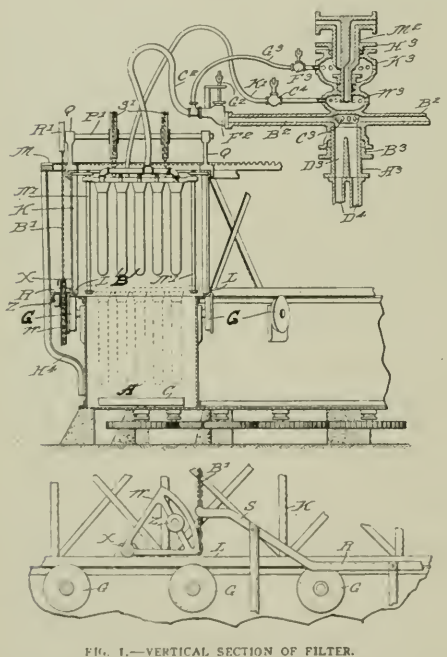

FIG. 1.—VERTICAL SECTION OF FILTER.

liquid is conveyed to a suitable chamber. As each set of filters approaches the partition between tanks *A* and *D* it is automatically raised from *A* and again automatically lowered into *D*, where the cake is washed during the progress of the filter through that tank. Arriving near the partition between *D* and *E*, the filter is again raised and kept in this position, with the vacuum still on until it arrives over tank *F*, where it is lowered and the cake discharged by compressed air admitted to the inside of the filter frame, and by a water jet directed against the outside. The filter is then ready to receive another cake on being automatically lowered into tank *A* containing the agitated pulp. (945,193, Jan. 4, 1910.)

Agitation.—The agitation of pulp or solutions in the treatment of ore by the cyanide process is effected by J. E. Rothwell and R. P. Akins, of Denver, Col., in a cylindrical tank with conical lower portion by means of pumping. The solution supplied to the pump comes from an overflow at the top of the tank and thus contains no large particles of pulp to wear the linings and working parts of the pump. The discharge from the pump enters the apex of the conical bottom, and carries with it any sands which may have settled at that point. The path of the discharge is upward through a vertical pipe placed in the center of the tank, from which it issues against a baffle or distributing plate. This causes the pulp solution to spread out evenly over the area of the tank, the heavy particles settling to the bottom and the fine slime again overflowing to the pump, to be forced upward through the

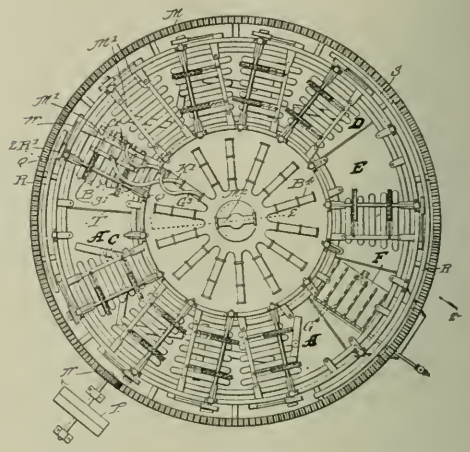

FIG. 2.—PLAN OF PLANT.

central tube, carrying the settled sand with it. A series of tanks may be used for continuous agitation and overflowing, the overflow from one tank to the next taking place through a special shape vane at the top of the tank which cuts out a uniform part of the tank content and carries it to the next tank. (951,742, March 8, 1910.)

Sand Treatment.—While the above two patents referred, one to the treatment of slimes only and the other to a mixed charge of sand and slime, a third interesting patent of a similar nature is that granted to Charles E. D. Usher, of Johannesburg, South Africa, for the treatment of sand only. Such material has hitherto usually been treated in vats by percolation, which is a slow process, and it is the design of the inventor to provide a more rapid means of treating this material. This is effected by providing in the bottom of a vat a number of radial perforated pipes connected with a central chamber. The ends of all the radial pipes are curved in the same direction with the circumference of the vat. A charge of sand having been placed in the vat, a solution of cyanide, for example, is forced in through the pipes and out of the perforations. The action of this solution is to stir the sands and to keep their surfaces bright and clean by attrition. The mass finally reaches a state of homogeneous semi-suspension. As soon as a sufficient quantity of solution is forced through the charge to collect in a layer at the top of the vat, the pump is disconnected from the sump from which the solution was being drawn, and connected with a decanter which rests in the upper surface of the liquid in the vat. The supply of solution is now continuously circulated through the mass of sand being injected through the radial pipes at the bottom and drawn off through the decanter placed in the clean layer at the top. The inlet of the decanter is usually so arranged that it draws in a quantity of air with the solution, thus providing an efficient aeration of the

mass in the vat. The process of solution and aeration is continued until the values are dissolved from the sand, whereupon the solution is drawn off and conducted to a suitable tank. The sands are then washed in the same manner as they were leached. (949,455, Feb. 15, 1910.)

Antimony.

Treating Arsenical Antimony Ores.—H. L. Herrenschmidt, of Paris, France, proposes to produce a clean antimony regulus from arsenical antimony ores by a combination wet and dry process. A preliminary roast of the coarse ore at a temperature of about 400° C. is the first step. The volatile oxides of arsenic, antimony and sulphur given off in this step are condensed for later use. The fine ores are not roasted, but are mixed with carbonate of soda and lime, with soda waste to which has been added carbonate or sulphate of soda, or with sodium sulphide. This mixture is then boiled with water under a pressure of four or five atmospheres. This operation forms antimoniates and arsenates of soda, or sulphoantimoniates and sulphoarsenates of soda, or all four. The liquor containing these salts is drawn off and is now caused to react with the oxides formed in the roasting operation before mentioned. Oxides and sulphides of antimony comprise the precipitate, while the arsenic dissolves in the solution of the arsenate or sulphoarsenate of soda. The antimony oxides and sulphides are collected and reduced to a clean regulus free from arsenic. Any antimony left in the liquor containing the arsenic may be precipitated by the sulphur dioxide from the roasting process, or by any other suitable means, while the arsenic remains in the solution. The inventor describes special apparatus for carrying out the process. (948,545, Feb. 8, 1910.)

Zinc.

Smelting Zinc Ores.—The recovery of zinc from lean zinciferous material, such as zinciferous slag or lean ores, may be effected by fine pulverizing and mixing with coal dust, briquetting the mixture and then charging these briquets into a furnace with small coal or coke. Zinc is volatilized and the other materials are slagged off. The object of a process patented by Hermann Pape, of Hamburg-Billwärder, Germany, is to eliminate as far as possible the necessity for grinding the material. He has determined that the quantities of reducing material contained in the briquets and the quantity of small coal or coke fed into the furnace with the briquets is more than sufficient to effect the removal of zinc from the briquets. Consequently he has found it possible to add to the ordinary furnace charge a considerable proportion of the zinciferous material in lumps, thereby avoiding the expense of crushing and briquetting. The manner of charging the furnace is, first, small coal or coke, second briquets of zinciferous material with carbon, third lumps of the zinciferous material. (948,740, Feb. 8, 1910.)

Alloys.

Improvement in Copper Alloys.—The manner of introducing certain other constituents into brass for the purpose of increasing its tensile strength and ductility is the basis of a patent granted to S. C. Peck and W. R. Hodgkinson, of London, England. Small proportions of chromium, manganese, nickel, cobalt or zinc may improve the quality of the alloy. The preferred manner of introducing these elements is by the addition of the phosphate of the metal with a reducing agent such as carbon, to a small quantity of copper or one of its alloys. This gives a metallic solution of the phosphide of the metal to be added, and this metallic solution may then be used to alloy molten brass in the desired proportions. In the second operation some of the zinc in the brass is volatilized as zinc phosphide, leaving the brass alloyed with the metal added. An actual test was as follows: 2600 grams of brass (Cu. 70 per cent, Zn. 30 per cent) were melted in a crucible with 200 grams of a mixture of equal parts of chromium phosphate and powdered charcoal. The temperature was about 1000°C. The addition of charcoal and chromium phosphate was repeated twice at intervals of an hour. After four hours heating the cast was made and this metal containing chromium phosphide was used to improve the qualities of brass as follows: 1516 grams copper and 655 grams zinc were melted together and to the melt was added 82.5 grams of the chromium phosphide brass. The resulting metal tested 19 tons per square inch tensile strength, and showed an elongation of 72 per cent on two inches. The same brass without the chromium phosphide added showed tensile strength of 14.4 tons per square inch and elongation of 38.5 per cent on two inches. (943,159 Dec. 14, 1909.)

Paper Mill Liquor.

Regeneration of Spent Liquor of Paper Mills.—The economical treatment of the spent liquor of paper mills for the recovery of the alkali and resinous matter contained forms the basis of a process devised by Isidor Kitsee, of Philadelphia, Pa. Heretofore, it has been the custom to concentrate the liquor to a syrupy consistency, after which the resinous matter is burned or carbonized. This residue is again dissolved in water, the carbonized mass filtered out and the caustic recovered. The process not only involves the loss of the resinous matter, but is inefficient in the recovery of the alkali. To overcome the objections to this process, the inventor causes the spent liquor to be electrolysed in a diaphragm cell. The spent liquor is placed in the anode compartment of the cell, while the cathode compartment contains water to which a little sodium chloride has been added. Through the action of the current, the sodium chloride is decomposed, the chlorine going to the anode compartment, while caustic soda is formed in the cathode compartment. The presence of the chlorine in the anode compartment acidulates the solution and causes the resinous matter to separate and coagulate. The result of the operation is the concentration of the alkali in the cathode compartment and the accumulation of the resin in the anode compartment. If little resinous matter is contained in the spent liquor and the chlorine is generated too abundantly, it may be led from the closed compartment to a tank of water, thus forming a suitable bleaching agent. (942,207, Dec. 7, 1909.)

Various Metallurgical Patents.

Roasting and Sintering Ores.—Metallurgists continue to give considerable attention to the preparation of fine ores prior to charging in the blast furnace. One of the latest patents on a process of this kind has been granted to Walter G. Perkins, of London, England, and Mark L. Requa, of San Francisco, Cal. The process resembles somewhat those patented by Dwight and Young in that there is a perforated hearth on which the charge is placed, the hearth lying above funnels and a tube connected with the exhaust apparatus. There is a marked difference, however, in that the hearth is stationary instead of movable as in the other patents mentioned. The ignition of the charge is effected by a blast of gas directed onto the surface of the charge under a hood. The hood is movable and as soon as ignition has commenced at any one point of the hearth, the hood is moved to another area. The exhaust continues until the entire charge is sintered. The hearth is hinged along one of its sides and in order to discharge the sintered mass the hearth is moved to an inverted position on its hinge and the entire sinter falls on to a perforated or slotted grating, through which the fine material falls, while the large lumps are discharged at a point convenient for smelting. (951,199, March 8, 1910.)

Still another sintering device is the subject of patent granted to George G. Vivian, of Tintic, Utah. This furnace is of the reverberatory type, and is operated by hand. Ore is fed in hoppers placed along one of the long sides of the furnace, the hoppers being water-jacketed. The furnace operator rabbles the mass over the hearth of the furnace and as soon as it becomes sintered withdraws it onto the cooling floor. To control the operation of the furnace means are provided for admitting cold air above the charge. (950,798, March 1, 1910.)

Joseph Weatherby, of New Cumberland, Pa., has been granted a patent for agglomerating fine iron ores. In a rotary kiln the fine material is not heated to the point of agglomeration until it reaches a point near the discharge end, where coke or charcoal is introduced and mixed with the ore. As the mass agglomerates at this point the carbon particles are consumed, leaving the ore in a porous condition suitable for smelting. The refuse coke dust discarded at the blast furnace has been successfully used. (949,387, Feb. 15, 1910.)

In order to overcome the difficulties arising from the formation of annular rings in kilns, August Brăutigam has made use of a blast of air directed at one point of the ring until it disintegrates. The operation may be performed while the furnace is either stopped or in slow motion, the effect being to so chill the ring at a certain point that it will crack, due to contraction. When the furnace is again placed in operation the balance of the ring falls off and mingles with the ore. (13,062, Dec. 28, 1909.)

An improvement in roasting furnaces of the superposed hearth type has been made by Utley Wedge, of Ardmore, Pa. The improvement relates to the construction of the furnace whereby the furnace arches and their superposed hearths are supported on an outer structure, so that the enclosing wall of the furnace is relieved of weight and strain. Economical construction and greater facility in making repairs constitute the main features of the improvement. (946,178, Jan. 11, 1910.)

Cooling Roasted Ore.—The economical cooling of roasted ore is of importance as an intermediate step in some metallurgical operations. Frank D. Baker, of Denver, Colo., accomplishes this in a rotary cooler with cone-shaped ends, revolving in a vat of water and having a spray of water directed along its top. The buoyancy of the water is of assistance in permitting the use of a longer cylinder than might otherwise be practicable on account of the necessity of bearings between the extremities of the cylinder. The cooler is rotated by any suitable power connection. At its discharge end it is equipped with internal spirally arranged blades which advance the ore to the opening. (943,294, Dec. 14, 1909.)

Electrostatic Ore Separation.—A patent has been granted to Frederick G. Cottrell, of Berkeley, Cal., on improvements in effecting interchange of electric charges between solid conductors and gases. One of the interesting applications of the principle involved is the electrostatic separation of ore. A metallic revolving roller, connected to earth, receives a steady supply of finely divided ore from a suitable hopper. In front of the roller, parallel with its axis, and slightly above its center, is a pubescent electrode in the form of a piece of cotton-covered magnet wire. This takes the place of the metallic discharge points usually used in machines of this type, and is the main feature of the invention. The inventor claims that all the advantages claimed for metallic points are obtained in higher degree by the use of fine filaments or hairs of a textile substance, even though it may not ordinarily be considered a good conductor. For example, such materials as asbestos, cotton, wool and silk are used. Suitable receptacles are provided beneath the roller to catch the conductive and nonconductive particles. (945,017, Jan. 11, 1910.)

Various Electrochemical Patents.

Copper Plating.—Dr. E. F. Kern patents a new electrolyte for copper plating. It is a solution of copper fluosilicate and ammonium fluosilicate (or,in some cases, aluminium fluosilicate) in water, and a further improvement may be obtained by the additional use of ammonium fluoride with an alkaline tartrate. For plating iron, steel, or zinc with copper, the bath preferably consists of 100 parts water, 12 copper fluosilicate, 8 ammonium fluosilicate, 6 ammonium tartrate, and 5 or more parts of ammonium fluoride. The bath is maintained neutral or slightly alkaline by means of ammonia. For coating brass, copper "or alloys of other metals," the bath preferably consists of 100 parts of water, 12 copper fluosilicate, 8 ammonium fluosilicate, 8 ammonium fluosilicate, 0.06 gelatine or tannin, and 5 or more parts of ammonium fluoride. In this case the bath is acidified by free fluosilicate acid or is maintained neutral by employing aluminium fluosilicate instead of ammonium fluosilicate. When the bath is used in acid condition, it is advisable to add gelatine or tannin to the bath in the proportion of one part of solid gelatin to one part of the concentrated extract of tannin to 2000 parts of the bath. A copper anode is employed. (946,903, Jan. 18, 1910.)

Nitric Acid from Air.—Mr. Francis I. DuPont, of Wilmington, Del., who has paid considerable attention to the production of nitric acid by electric discharges through air, has been granted another patent for a furnace for this purpose. It is shown in Fig. 3. The air is passed through a silica tube *a* within which are the electrodes *b*, between which the arc *k'* is formed. The silica tube is surrounded by the glass tube *h* through which a cooling liquid is passed from *j* to *k*. The field magnets or rings *l* are energized by a polyphase current, thus producing a rotary magnetic field which causes the arc to

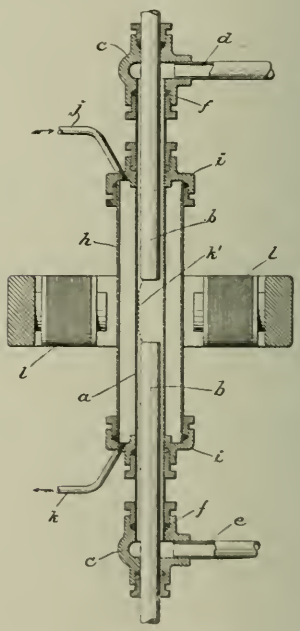

Fig. 3.—Nitric Acid from Air.

rotate around the inner surface of the silica tube. Air is forced through the passage *e* into the zone between the electrodes; it is heated by the rotary arc (so as to form nitrogen oxide), but as soon as the rotating arc passes from any portion of the air, this air is immediately subjected to the cooling action of the walls and its temperature is so rapidly reduced as to prevent the formed nitrogen oxide from being again largely decomposed. (950,703, March 1, 1910.)

Ozone.—Mr. Robert W. Rice, of Cleveland, Ohio, patents an ozonizer in which glass plates serve as dielectrics, being placed between aluminium plates. These are punched so as to provide a series of discharge points. A transformer is provided in the lower part of the apparatus. (930,347, Feb. 22.)

A large number of electrochemical patents had to be reserved on account of lack of space for our next issue, in which all electrochemical patents will be brought up to date. Several abstracts of patents of an electrochemical nature will be found above among the patents on Iron and Steel and Copper.

Smelter Fumes and Damage Suits.

By R. G. Burton and Taft Reed.

A most interesting conflict of interest between the agricultural and lumbering industries on the one hand and the metallurgical and chemical industries on the other is now being brought into more and more prominence. Ever since sulphuret ores have been smelted there have been complaints from the surrounding agriculturists, and the early law cases of England are replete with decisions on the respective rights of the parties. In the majority of cases the issue turned upon the strict right of the agriculturists and the preservation of their property against even a technical invasion by the gases and smoke from the smelters. The same conditions have prevailed for many years in Germany, and now in America the question is becoming one of greater importance than ever before. The clash has become almost a battle for very existence.

The increase of population has greatly increased the value of foodstuffs so that the agriculturist has the better right—where actually injured—to bitterly complain; where the forests a few years ago were regarded as practically worthless, having in same cases really nominal values, they have now suddenly become enormously valuable on account of their fast disappearance and a real injury to them represents a real loss of value. On the other hand, the great increase in population has given a great impetus to all metallurgical and chemical developments, with the result that any interference with these industries must inevitably mean not only serious loss to the operator, but to the public as well. Civilization demands electricity, electricity demands copper, as expanding industry demands steel, which in turn requires coke, and as the copper furnace or coke oven is interfered with in its operation, from whatever cause, so civilization must be inconvenienced and must in the end sustain a loss. What is true of the loss or injury occasioned in the manufacture of copper or coke, is, of course, true of all those commodities which in their manufacture cause to be thrown off gases deleterious to vegetation, so that on the side of copper and coke are arrayed zinc, lead, wood-pulp, commercial fertilizer and a dozen others.

"But," says the farmer or lumberman, "I am at least entitled to be paid a fair price for my timber damaged or my crops destroyed." True, but the question will arise, "Where is the dividing line. What has been killed or injured by the gas or fumes and what by the weather or other natural causes?"

It is just at this point that the real trouble begins. It is no longer a fight between agriculture on the one side and industry on the other. The matter has narrowed down to one of lawyers and courts, and most important of all, to the question of evidence. The plaintiff may be honest, his crop or his woodlands may have been injured, but in practically every case, honest though he be, his injury, to his mind, has been done solely by his neighbor who mines and smelts and cares nothing for farms, natural causes of death are lost sight of, prospective crops would have been enormous, the stand of timber and its value are prodigous and the damage to it is most pitiful to see. And those orchards! They were not infested with scale and blight and diseases innumerable and they received the best of care and attention and were of the hardiest and most valuable varieties.

So long as the crops, the orchards and the timber were of little value, the evidence required usually went only to the point of showing the fact of death and the fact of the proximity of a smelter. But now that the values of crops and particularly of timberlands have increased and will increase so enormously, the question of cause of injury will become more and more vital. What was once in a haphazard way almost conceded is now coming to be analyzed, and the true conditions so long really incomprehensible to the courts, and to the defendants as well as to the plaintiffs, are coming to be understood. Scientifically trained men have been investigating the conditions and have studied those natural causes either wholly responsible or acting as contributing factors in the damage complained of and the following surprising condition has been found: That in almost every case insects, fungi, and worst of all, fire and dessication, have been working a great part of the injury for which the smelters have been blamed and for which they have had to pay handsomely.

Damage to the forest by insects is caused either by those which kill the tree outright, or by those which weaken the tree and reduce its commercial value. Millions of feet of timber are killed each year by bark-beetles of the genus *Dendroctonus,* which attack conifers, in certain parts of the country destroying whole forests. To another beetle, *Agrilus bilineatus,* is attributed the death of most of the mature chestnut trees in the United States. One of the Scolytids, *Scolytus quadrispinosus,* has caused most of the death of hickory in the past few years in the southern Appalachians. These are only a few prominent examples of insects causing serious damage to the forest trees and could be greatly multiplied.

The ravages of fungi are seen everywhere and in all parts of the country. A striking example is the "white pine blight" which causes a discoloration of the leaves exactly similar to that caused by smelter fumes and like them causes the death of the tree. Another fungus is *Diaporthe parasitica,* which is now killing off the chestnut in the vicinity of New York City.

Worst of all, however, is the damage, direct or indirect, done by the forest fires which are more or less prevalent everywhere. In the Appalachian system, for instance, the soil is gradually but surely reaching a condition of barrenness due to the constant firing at the wrong time of year by the farmers under the mistaken belief that the value of the land for grazing will be enhanced. The common idea that fires must be severe in order to do serious damage is erroneous. A light ground fire running over the ground year after year dessicates the soil by destroying the ground litter and humus, paves the way for the inroads of insects and fungi and for the beginning of erosion; in short, disturbs the normal balance of things in the forest to such an extent that the trees are killed just as surely as though girdled by severe fires.

In view of the foregoing facts, it will be readily seen that the best and only defense for the smelting company to adopt is based on the collection of evidence in the field, section by section and township by township, which will show the relative damage done by smoke, by fire, insects, fungi and other causes. The criteria of smoke damage in such a field examination are at once simple and complex. The different causes of death, including smoke, and how each acts, may be perfectly understood, but it is almost always the case in the forest that death is due to no one cause, but to a combination of several causes. Thus, fire may scar a tree and afford entrance to insects or fungi, which in turn so weaken the tree that it falls a victim to smelter fumes, which it would otherwise have resisted.

Over large areas perhaps no one cause can be fixed upon as acting alone, and this fact would at first seem to negative a defense along these lines. It will be plain upon brief consideration, however, that it is only necessary to show that there are other causes than smoke playing a large part and the burden of proof immediately falls upon the prosecution to show how much of the damage has actually been done by the smoke, and unless he can accomplish this, his case at once falls to pieces. The judge is justified in instructing the jury, as has been done in recent cases, that unless they can settle upon the actual amount of damage by smoke, beyond all reasonable doubt in their own minds as to the accuracy of the figures that they thus fix upon, that they shall bring in a verdict of nominal damages only. This method of procedure denies to no one his opportunity for recovery by law for any damage traceable to the influence of smelter fumes. But it forces the plaintiff to substitute facts for theories and a detailed examination of the conditions for exaggerated ideas of his injury. Not even the defendants themselves have usually any idea of how small a part of the injury they are perhaps responsible.

To sum up, the financial importance to the smelting company of collecting evidence in the field of every cause other than smoke, which has killed or damaged the forest, cannot be overestimated. What special form these other causes of death will take varies greatly with the locality and can only be determined by a field examination of the particular region in question.

Automatic Gas Calorimeter.

The automatic gas calorimeter, which is built by the Sargent Steam Meter Company, of Chicago, has recently been improved in various details. A description of the improved instrument should, therefore, be of interest.

Fig. 1 shows the complete calorimeter. It consists of a wet test meter in which the gas consumed is accurately measured.

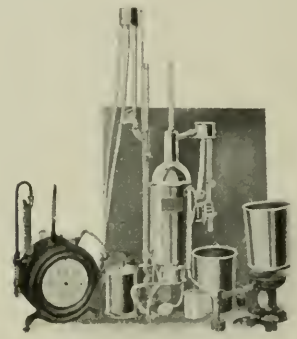

FIG. 1.—COMPLETE CALORIMETER.

From this meter it flows to a governor which maintains a uniform pressure of the gas at the burner. In the calorimeter proper the accurately measured gas is burned and its calorific value is manifested in the rise of temperature of measured quantities of water flowing through. From the calorimeter the heated water for each unit of gas burned is automatically discharged into one of the pails in which it is weighed on the decimal scales. The pounds of water, times its rise in temperature in degrees Fahrenheit, times the quantity of gas in cubic feet consumed gives the b.t.u. direct.

Meter.—Fig. 2 is a sectional elevation of the meter. The rotor is accurately balanced, and is mounted on a heavy shaft to which is attached the integrating train. The meter rests on three legs, each equipped with a leveling screw. A circular sensitive level permits of accurate adjustment. The water level is indicated in the glass gage by a pointer set in the laboratory of the makers, when the meter is calibrated, and when it is operated under similar conditions it will give absolutely correct results. A thermometer indicates the temperature of the gas metered and a manometer its pressure, both of which are necessary in reducing metered to standard gas.

One revolution of the needle equals one-tenth of a cubic foot and as the dial, made of white porcelain, is divided into 100 parts, the meter has a range before repeating from one-thousandth of a cubic foot to 100 cu. ft. A filling funnel and drain facilitate its manipulation. When the meter is used with the calorimeter, the electrical attachment closes a circuit for every tenth of a cubic foot measured, which through the dumping bucket automatically segregates the water whose temperature is raised by the unit of gas burned.

Pressure Governor.—In order to maintain a non-pulsating flame at the burner, a pressure governor is required between meter and calorimeter. The governor shown in Fig. 1 is of the inverted bell displacement type and can be adapted for any gas by the adjustable weights.

Calorimeter.—In the calorimeter every heat unit given out by the combustion is manifested in the rise of temperature of the water flowing through while a unit of gas is burned. It is mounted on three wide spreading legs, insuring stability, each of which is provided with a leveling screw so that it can be operated on a irregular surface.

Fig. 3 is a section of the instrument in which the inlet water, having a constant head at the wier *A*, the temperature of which is taken at *B*, passes down the tube *C*, and enters the calorimeter at *D*. Here the water is spread around the bottom of the instrument by the baffle plates *E* and *F*, and then flows upward around the tubes *G*, through which the products of combustion pass. The partially heated water on leaving the tubes spreads out over the dome sheet *H*, where it is heated by the hottest gases and then passes to the wier *K*, through the baffle plate *I* and around the thermometer *J*, where the outlet temperature is taken. From this wier *K* the water is discharged into the automatic tipping bucket, which delivers the heated water alternately to the copper pails.

The combustion of gas takes place in the central flue at *L*, the products of combustion passing upward to the dome sheet and then down through the flues in a contrary direction to that taken by the water. The gases are discharged at *M*, where the temperature is maintained the same as that of the surrounding air by the damper *N* and the quantity of water flowing through.

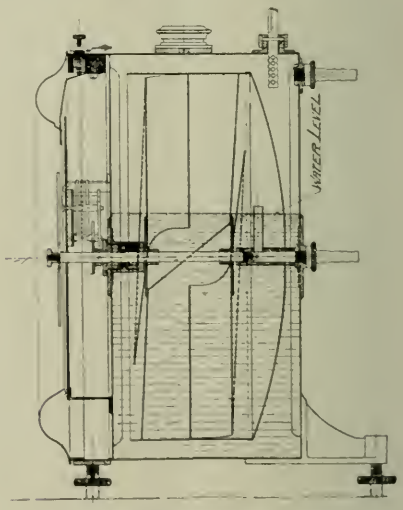

FIG. 2.—SECTIONAL ELEVATION OF METER.

Accessories.—The special Bunsen burner, adjustable for any gas, extends well up into the internal flue and the closed base prevents downward radiation. By means of a fixed mirror the operator can always see the color of the flame through the air admission opening. Two dry cells furnish the electric current for operating the releasing magnet and the weight of the water in the bucket tips it. The scales have a capacity of 10 lb., are graduated to a hundredth of a pound and when balanced with the empty pails indicate the net weight of water, whose temperature has been raised by the combustion of a 1/10 cu. ft. of gas.

With this calorimeter determinations may be made for every 1/10 cu. ft. burned, covering an interval of time from one to three minutes, and for an unlimited duration. With such a log, continuous curves of a calorific value of the gas may be plotted and an absolute record of the operation of the gas-generating apparatus may be obtained and preserved.

When extreme accuracy is required in reducing metered to standard gas, a special draft gage is used to get the pressure of the gas at the meter. It is used in connection with producers, furnaces, and ventilating apparatus.

The foreign matter in gas is determined mechanically when it is tested for its calorific value or by a separate operation.

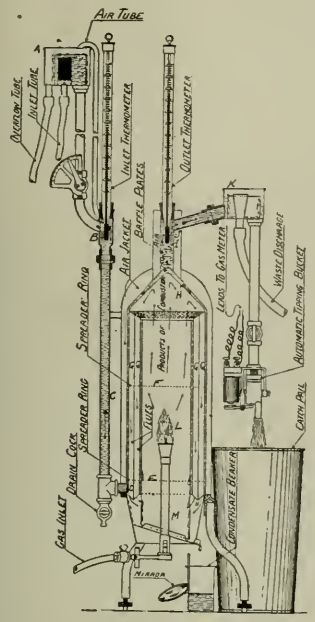

FIG. 3.—SECTION OF CALORIMETER.

In either case the unit of gas analyzed is determined by the meter. The tar in producer gas, the dust in blast furnace gas, the moisture in any gas or air, and the dust in the atmosphere is determined by special filtering apparatus, built by the Sargent Steam Meter Company.

Centrifugal Compressors for Oil Burning.

By S. A. Moss.

The use of crude or partially refined petroleum as fuel for industrial purposes is rapidly extending. Taking into account convenience and cleanliness, oil is a cheaper fuel than coal for many industrial purposes. For this reason oil is being used to an increasing extent for forging, hardening and tempering in blacksmith shops; baking cores and melting in brass, iron and steel foundries; smelting, melting and refining in metallurgical establishments, and for a great variety of other processes where high temperatures are desired.

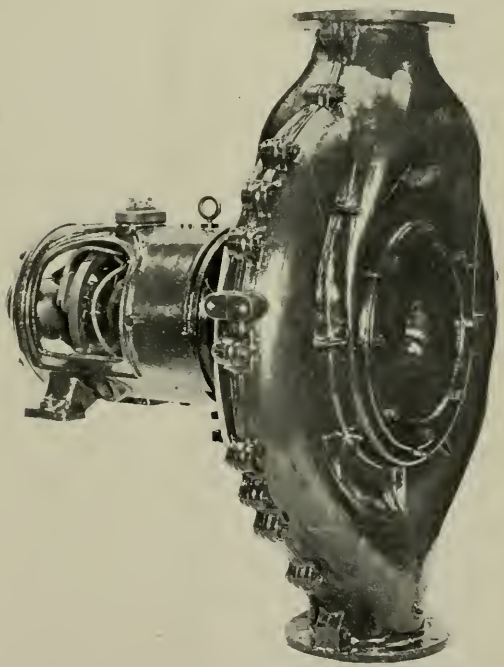
Oil is also used under steam boilers in many cases. However, space will not be taken for detailed discussion of this application.

The furnace usually consists of a chamber (often of very large dimensions), lined with fire brick, upon the floor of which is placed the object to be heated. The oil, together with some of the air for combustion, enters at one side from one or more jets, and the burning blast impinges on the object to be heated. Sometimes the chamber is rectangular, and the jets are directed immediately upon the object. In other cases there are bays or side chambers to give opportunity for complete combustion previous to the main chamber. There must, of course, be an outlet for the products of combustion after they have given up their heat. As can be seen, a furnace of this type is much simpler than one where coal is used as fuel, for with coal there must be a grate, a combustion chamber and an ash-pit. There is, in addition, the expense of firing, clinkering, and removal of ashes. Oil fuel is usually stored in tanks and delivered by pumps, and the storage and delivery is usually a simpler problem than that of coal.

So far as cost of a heat unit is concerned, coal is possibly a cheaper fuel at the present price of oil. However, taking into account all of the incidentals, the total cost with oil is in many cases much less.

Two kinds of oil are in use at the present time. One is crude oil just as it comes from the well, while the other is a residue remaining after some of the more valuable products have been extracted. The nature of this residue varies considerably at different places and at different periods.

In order that the oil may burn in a proper manner and in a reasonable space, without smoke, it must be intimately mixed with the air necessary for combustion. The oil is, therefore, reduced by a "burner" to very small drops, each surrounded by air for its combustion. This is called atomization. The drops must be of very small size, since a drop of appreciable size,



CENTRIFUGAL AIR COMPRESSOR.

even though it is surrounded by the entire amount of air necessary for its combustion, will proceed for a considerable distance from the burner, as a small ball of yellow flame, before it is completely burned.

The burners for producing the proper type of jet are of many shapes. There is always a pipe carrying oil under pressure leading through the burner. There is usually an additional pipe carrying compressed air or steam for the atomization. In the case of oil burners for steam boilers, the jet is usually steam, while for industrial purposes, the jet is usually compressed air. Some of the air for combustion is entrained or sucked in by the velocity of the jet issuing from the burner. In the case of steam atomization, the entire amount of air

must be supplied in this way. With air atomization the amount supplied under pressure and the amount entrained differ with the type of burner. There are many standard burners on the market and in addition many of the plants which burn oil have special devices of their own. The arrangements are, therefore, numerous and no general description can be given. There are the following general classes, however:

The compressed air may be supplied at a pressure from 15 lb. to 30 lb. per square inch. In such cases, the compressed air usually forms a comparatively small portion of that necessary for combustion, and the main air is entrained by the high velocity or sucked in by the chimney draft. In one such system, the main air is supplied by a forced draft given by a fan blower delivering the air through a pipe ending near the burner, at a comparatively low velocity.

In other cases, the compressed air is supplied at a pressure of from 1 lb. to 4 lb. per square inch. In these cases, probably the greater portion of the air is supplied, and a comparatively small amount is entrained. However, it is difficult to make a positive statement in this matter. The designers of the various burners usually have an idea regarding the amount of air to be supplied, although this idea is often very approximate.

The General Electric Company have a standard line of single-stage centrifugal compressors from 5 hp to 350 hp for pressures of from 1 lb. to 4 lb. per square inch, and these are very well adapted for use with oil burners. Multi-stage machines are also made for pressures from 15 lb. to 30 lb. per square inch, and these have also been furnished for the same purpose.

These compressor sets are self-contained and are direct-driven by Curtis steam turbines, induction motors or direct-current motors. They have no wearing or rubbing parts and consequently, no matter how long they are in operation, there is no falling off in pressure and output due to leakage. The pressure is steady and free from pulsations.

Notes.

Colorado Iron Works Company's Impact Screen is the subject of a pamphlet, 9-B, issued from the Denver office. The screen is designed to take the place of trommels and hydraulic sizers in certain work. Recent minor improvements make the device thoroughly dependable for hard work.

Vanadium steels are now made in a variety of types suited to special purposes. Vanadium toughens steel directly by solid solution in the carbonless portion, and indirectly by removing oxides. The American Vanadium Company, Pittsburgh, has set forth qualities and uses of vanadium steels in a booklet recently issued. Test tables and microphotographs show the strength and structure of the steels. To extend their market, they have also recently published interesting pamphlets in French and German entitled Les Aciers au Vanadium and Vanadium Stahl respectively. Interesting information is given on the heat treatment of vanadium steels, the methods of employing vanadium in iron and steel, and results. Copies of these nicely illustrated books are sent to interested parties on request.

Power from Exhaust Steam may be obtained through turbine engines and greatly increases the efficiency of the power plant. The American Regenerator Company, Chicago, has explained in a pamphlet recently sent to us the operation and use of its regenerators for heat storage between the exhaust of reciprocating engines and the turbines.

Metal Statistics are neatly presented in a small volume of that title issued by the American Metal Market Company, New York. Iron and steel, copper, tin, spelter, lead, antimony, gold and silver are considered.

International Exhibition of Railways and Land Transport.—The Argentine Republic will celebrate the 100th anniversary of its political emancipation by an industrial exhibition to be held at Buenos Aires, May to December, 1910.

Ferroinclave, a sheet steel reinforcement for concrete work, is illustrated and described in a new catalog issued by the Brown Hoisting Machinery Company, Cleveland, Ohio. Ferroinclave is a sheet steel with dovetail corrugations, and is used in the construction of roofs, floors, walls, stairs, bridges, tanks, coal bins, etc.

Pneumatic Separators.—By the proper arrangement of air currents, deflectors and chambers all light, powdered materials may be handled with uniform results and remarkable precision. It is the design of Osborne pneumatic systems to accomplish this. These systems are adapted to removing waste from grinding machinery, separating and grading crushed products, washing dust from fuel gas, and neutralizing the fumes from chemical operations. A catalog of the Griscom-Spencer Company, 90 West Street, New York, explains in detail the operation of the Osborne system.

The Mineral Production of Canada for 1909 has been compiled and is being distributed by the Minister of Mines, at Ottawa.

Fire Brick.—A catalog received from the Scioto Fire Brick Company, Sciotoville, Ohio, describes high-grade firebrick manufactured for various purposes. The analysis of the clay from which the brick are made shows it to be almost pure silicate of alumina.

Transite Asbestos Wood is a fireproof building material made by the H. W. Johns-Manville Company, New York. The material is mineral in character, but can be handled and worked just like wood.

The American Lava Company, Chattanooga, Tenn., manufactures machined insulating articles known to the trade as lava, but being in reality a talc which hardens upon being subjected to a high temperature. Quite a variety of insulators, gas burners, etc., are made in this manner.

Eimer & Amend, New York, have issued their 1910 edition of the catalogue of chemical apparatus. This is a very full and exceedingly interesting publication which should be in the hands of all users of chemical apparatus and chemicals.

The Ammonia-Cyanide Process for treating copper, gold and silver ores is a development by Western metallurgists who have organized the Ammonia-Cyanide Engineering Company, of San Francisco. The principle of the process is the leaching of ores, precipitating the dissolved copper by boiling out the ammonia in tight apparatus and then precipitating gold and silver by zinc dust or shavings in the usual manner. The ammonia boiled out of the solution is condensed for re-use.

The Control of Combustion in the boiler plant is the aim and object of the Sarco CO_2 recorders, made by the Sarco Fuel Saving & Engineering Company, of New York. A recent catalog describes their device for automatically recording the CO_2 in the flue gases. Other catalogs deal with the company's pyrometers, calorimeters, recording draught gages and recording steam meters.

The New York Metal Exchange has issued its statistical review of the domestic and foreign metal markets for 1910. The production and prices of tin, copper, lead, spelter, iron and steel, antimony and silver in the various markets of the world are given.

Water Gage Glasses break from contact with cold drafts of air or liquids while the glass is heated. A new German gage glass, known as "Sonderglass," is made by fusing two separate tubes into one, thereby giving increased strength and allowing for expansion and changes of temperature. A. W. Chesterton Co., Boston, are importers into this country.

Ozone. As an instance of the progress which ozone is now making in water sterilization it may be mentioned that the city of St. Petersburg, in Russia, has installed an ozone plant for the treatment of 10,000,000 gal. of water a day. The system of ozone generation of the Siemens & Halske Company is being used. Further progress is also reported from several German and Austrian cities. Ozone ventilators for the purification of air in rooms are stated to find increased favor.

Cupel Machine.—The Denver Fire Clay Co., of Denver, Col., has sent us a description of Iler's cupel machine, which with the improvements recently made, has a capacity of 500 cupels per hour. It is operated by foot power, and the density and thickness of the cupels are regulated by one small set-screw on the pedal. The Iler cupel machine is made in two sizes, one making 1¼-in. and 1½-in. cupels, and the other making, 1¼-in. 1½-in. and 2-in. cupels.

Liquid Chlorine.—While in former years the liquid chlorine used in this country for various chemical and metallurgical purposes was imported from Germany, various American manufacturers have taken up the manufacture of liquid chlorine during the last year. Among them are the Castner Electrolytic Company, the Hooker Electrochemical Company, the Electro Bleaching Company and the Goldschmidt Detinning Company. From a statement of the Electro Bleaching Company we learn that they are entering the market prepared to supply any quantity of liquid chlorine from 100 lb. up to carload lots—18,000 lb. minimum. It is shipped in steel cylinders or drums holding approximately 100 lb. each.

Concrete Mixer.—We have received from the Chain Belt Company, of Milwaukee, Wis., their illustrated catalog 39, giving details of construction of their chain belt concrete mixer. This is a "batch" mixer of the "non-tilting" or chute-discharge type. A power loader is employed instead of the standard charging hopper. While the Chain Belt concrete mixers are furnished with steam, gasoline or electric power as desired, steam is thought to be the most reliable and economical under general conditions.

Combination Induction Furnace.—The firm of Pilger & Neidhart, in Frankfurt-Bockenheim, Germany, is erecting a combination induction furnace of the Roechling-Rodenhauser type for the manufacture of steel castings from electric steel.

New Blast Furnace.—The new furnace of the Andrew & Hitchcock Iron Company, Hubbard, Ohio, was successfully blown-in on Feb. 19, this year. This is the first of the new furnaces to go into operation this year. It is the latest type of furnace, designed and built by Mr. Julian Kennedy, of Pittsburgh, Pa., and Mr. Arthur E. L. Dette, engineer in charge of construction. The William B. Pollock Company, Youngstown, Ohio, furnished the iron work, and the Stowe-Fuller Company, of Cleveland, Ohio, all the firebrick. Niles brick were used for furnace lining, National brick for the stoves, and Empire brick for pipes and connections. The furnace, stoves, and connections make one of the best and most complete blast-furnace plants in the Mahonning Valley.

Industrial Enginering and the **Enginering Digest** have been consolidated into one paper under the name *Industrial Engineering and the Engineering Digest.*

The **Schaeffer & Budenburg Manufacturing Company,** 963 Kent Avenue, Brooklyn, N. Y., have sent us their catalog on indicating and recording pressure and vacuum gages, ammonia gages, hydraulic gages, draft gages, etc. Among the gages described is a new draft gage which indicates a pressure or draft of 1/100 in. of water column. It is fitted with a large, easily read dial.

California Mining Bulletin.—The California State Mining Bureau has just issued a bulletin dealing with the mineral productions and mining laws of that state. There is also included a set of county maps.

Pacific Smelting and Mining Company has issued to its stockholders the first annual report, showing the property owned by the company and the status of development. The company's office is 42 Broadway, New York, and the mines and smelter are located at Fundición, Sonora, Mexico.

The United Iron Works Company, Springfield, Mo., has recently issued a catalog of concentrating machinery. General milling machinery for ore-dressing is described and illustrated. The company makes a specialty of electromagnetic separators and manufactures the Cleveland-Knowles separator.

Electrostatic Ore Separation is the title of a booklet which we have received from the Huff Electrostatic Separator Company, Boston. A brief explanation of the principles and application of electrostatic separation of minerals is given. This interesting new separator will be described in detail in our next issue.

Testing and Research Laboratories of E. S. Lincoln, Brookline, Mass., are described in a booklet which he has just issued. Testing and research work of any description in the electrical field is undertaken.

The Pacific Tank Company and the **National Wood Pipe Company** announce a business consolidation under the name of Pacific Tank & Pipe Company. The company has factories on the Pacific Coast, and offices in the Equitable Bank Building, Los Angeles, Cal. A new factory has just been completed at Portland, Ore., which is the largest of its kind.

The Year-Book for Colorists and Dyers, published by Herman A. Metz, New York, has been received at this office. The book contains much very useful information of interest to the trade.

Oxygenite is an electrolytic product in the form of a gray pulverulent mass resembling fine sand and possessing the property of releasing when heated all of its contained oxygen. This amounts to about 5¼ cu. ft. of gas per pound of oxygenite. The material burns slowly, without a flame, and can be kept almost indefinitely, even if exposed to the atmosphere, without deterioration. It is valuable for generating oxygen for oxy-acetylene welding plants without having recourse to buying compressed oxygen in tubes. The oxygenite process and the machinery used in its application are controlled by the Industrial Oxygen Company, New York.

Davis-Bournonville Company reports a great advancement in cutting steel by the oxy-acetylene process. A 6-in. steel shaft requires 3 minutes to cut at a cost of about 37 cents. A 3½-in. steel plate has been cut 18 ft. in 26 minutes, and a 6-ft. cut was made in ⅝-in. steel in 2 minutes and 29 seconds. Other excellent performances consisted in cutting 84 ft. of ¼-in. steel in one hour, and a circle of 19½ in. circumference out of 1-in. plate in 45 seconds.

Export Office Opened.—The General Fireproofing Company, of Youngstown, Ohio, has opened an export office at 396 Broadway, New York City, in charge of Mr. A. D. Level, who has been for several years with the United States Steel Products Export Company.

Cyanide Plant Opens.—The old mill of the Natividad y Anexas Mining Company in the Sierra Juarez district, State of Oaxaca, Mexico, has been closed down and the ores will be treated by the new cyanide plant, which has just been finished.

Forge Shop Furnaces.—The W. S. Rockwell Company, of New York City, have sent us their catalog No. 8, on their forge shop furnaces operated with oil or gas fuel, for forging, flanging, plate heating, angle-bending, spring-fitting, case-hardening, tempering, annealing, etc. The catalog gives data on the various sizes in which these furnaces are made, with diagrams showing their construction.

Nationality of Inventors of Electric Steel Furnaces.—In a recent lecture on electric steel furnaces the following somewhat amusing remark was made by Mr. Viktor Engelhardt, chief engineer of the Siemens & Halske Company: "The inventors of the most important arc furnaces for steel making are Frenchmen like Heroult and Girod, or Italians like Stassano. The inventors of the induction furnaces are of the Teutonic or Anglo-Saxon races: Kjellin, Frick, Gronwall are Swedes; Colby, an American; Roechling and Rodenhauser are Germans. One might make the paradoxical remark that the types of the furnaces are in conformity with the race characteristics of the inventors. The arc furnaces spark with a noise and brilliant flame suggesting more fire than there is really in them. The induction furnaces behave in the reverse way. Their cooler outside appearance does not suggest at once how much heat is available in their interior."

Personal.

Dr. **Richard Amberg**, formerly manager of a carborundum company in Southern Switzerland, is now connected with the Indiana Harbor, Ind., plant of the American Steel Foundries, where an electric steel furnace is in operation.

Mr **A. J. Bettles**, of Salt Lake City, has resigned his position as consulting metallurgist to the Utah Copper Company, and expects to devote his time to private interests. He has been closely identified with the progress of metallurgy, and particularly ore dressing, in Utah for a quarter of a century.

Mr. **J. W. Coyle**, who was connected with the Best American Calorific Company until they retired from business, is now with the Rockwell Furnace Company, making a specialty of oil and gas furnaces for railroad work. Mr. Coyle is an experienced railroad man, having formerly been master blacksmith for the Lehigh at Wilkes-Barre, and later in charge of the drop-hammer and machine department at the forge shops of the Reading, at Reading, Pa.

Mr. **J. V. N. Dorr**, metallurgical engineer of Denver, and the inventor of the classifier and pulp thickener known by his name, has recently been in San Francisco on professional business.

Mr. **L. C. Hammond**, formerly at the head of the sales staff of the Denver Engineering Works, has accepted a similar position with the Central Colorado Power Company. Mr. P. D. Grommon has been placed in temporary charge of Mr. Hammond's work.

Mr. **Lafayette Hanchett**, formerly of Colorado, but later identified with the Newhouse interests in Utah, has left for an extended world tour, having sailed from San Francisco last month.

Mr. **H. W. Hardinge**, the inventor of the Hardinge conical-tube mill, of New York City, is on a professional trip and will visit the Lake Superior copper district and the famous Cobalt, Canada, silver district.

Mr. **C. A. Heberlein** has recently returned to the City of Mexico from an outlying district, where he has been erecting a smelting plant.

Mr. **A. B. W. Hodges**, who has for some years been general manager of the Granby Consolidated Company in British Columbia, has recently resigned his position, and will assume the general managership of the Cerro de Pasco Mining Co. in Chile

Mr. **D. C. Jackling**, manager of the Utah Copper Co., has left Salt Lake City on a trip to Colorado Springs, from which place he will go to Ray, Ariz., to inspect some copper properties.

Mr. **E. M. Johnson** has recently resigned his position as metallurgist at the Collinsville, Ill., plant of the St. Louis Smelting & Refining Company.

Mr. **F. H. Nickle** has resigned his position as engineer for the Pennsylvania Salt Manufacturing Company, at Wyandotte, Mich., and will specialize in vacuum evaporating work and salt-plant engineering. Mr. Nickle is associated with the firm of McDonald & Nickle, with headquarters at Detroit.

Mr **W. H. Oldham** has recently been appointed general blast-furnace superintendent for the Birmingham Coal & Iron Company, Birmingham, Ala.

Mr **William Scallon**, who formerly resided at Butte, Mont., where he was president of the Anaconda company and Western manager of the Amalgamated company, has removed to New York, where he will be permanently located at Hotel Netherland. Mr. Scallon will engage in the practice of law and will have no connection with the companies mentioned.

Mr **Charles F. Shelby**, formerly with the Phelps Dodge Company in Arizona, and later superintendent at the Greene-Cananea, in Mexico, has accepted a position as smelter manager with the Cerro de Pasco Company, in Peru.

Mr. **E. R. Wooley**, president of the Utah Ore Sampling Co., has returned to Salt Lake City, from an Eastern trip

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matters and in chronological order

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Electric Furnaces (*Continued*)

657,202, Sept. 4, 1900, H. C. McBrair, of Middletown, N. Y. Resistance type. A dental furnace for firing porcelain, in the form of a box having a hinged cover. The joint between the base and cover lies in a plane inclined downward toward the front. The base and cover are of metal lined with fire-clay. A platinum resistance-wire is embedded in the inner face of each part. Contact springs and pins connected with the hinges complete the circuit.

657,911, Sept. 18, 1900, G. D. Burton, of Boston, Mass. Resistance furnace for reducing ores containing gold, silver, sulphur and arsenic. The current used is from 6000 amp to 7000 amp at from 4 volts to 16 volts. The furnace has a vertical resistor chamber surmounted by a short stack, both consisting of carbon or of an alloy of copper, three parts; antimony, two parts, and tin one part. The upper and lower ends of the chamber are surrounded by massive clamps of copper, serving as terminals. The lower clamp has a plate closing the lower end of the furnace, and is hinged to drop down. The chamber is surrounded between and above the electrodes with clay, and may be lined with clay. An inclined feed-pipe opens into the stack. This pipe and the stack are closed by caps. Pipes serve for the introduction of steam and air, to assist combustion and chemical action. A pipe leading to an eduction-pump and water condenser serves to draw off sulphur and arsenic vapors. The furnace has steam and air gages and a pyrometer. Combustible matter may be mixed with the ore charge. By gradually raising the temperature of the charge, lead, silver and gold, or lead, antimony, zinc, etc., may be successively smelted and separately drawn off. The furnace may be used for separating bullion and for producing calcium carbide.

658,315, Sept. 18, 1900, A. H. Cowles, of Cleveland, Ohio. Arc or resistance type. The electric furnace proper is a chamber with solid carbon walls, constituting one electrode, and receiving a depending carbon electrode. The depending electrode is adjustably carried by a water-cooled stem passing through a stuffing-box. Ore-hoppers with double valves open into the top of the chamber. At each side of and connected with the smelting chamber are chambers with carbon walls, receiving coke supported on a grate beneath. Each side chamber communicates with hot-blast stoves or regenerators for supplying heated air and gas. Valved fuel-hoppers open into the upper ends of the side chambers. The walls and hoppers are water-jacketed and cooling coils may be embedded in the walls and cover. In operation, heated air and gas are introduced into one side chamber and pass through the body of coke therein, effecting combustion. The products of combustion then pass through the charge of ore in the intermediate electric furnace, preferably not through the zone of highest temperature, and thence through the body of coke in the other side chamber, escaping to the regenerators. The flow of gas and air is periodically reversed. The furnace may be used to reduce "lime, clay, sand, aluminium, etc."

658,536, Sept. 25, 1900, G. M. Westman, of New York, N. Y. Resistance type. Furnace for treating ores containing arsenic and precious metals. The furnace chamber is of fire-clay, with a removable lid carrying a valved hopper. The smelting chamber is a trough, the bottom of which is recessed at each end to receive water cooled cast iron electrodes. The exposed upper ends of these electrodes may be curved to the shape of parabolas, to increase contact with the ore. The charge, which

may be an arsenical ore containing iron, e. g., mispickle, carries the alternating current and is heated thereby as a resistor. The liberated arsenic escapes through a pipe to settling chambers and a water condenser. The melted ore free from arsenic, molten iron sulphides, or mattes, are tapped off. Much of the gold and silver sinks downward and may be absorbed by pools of lead over the electrodes.

658,698, Sept. 25, 1900, C. S. Bradley, of New York, N. Y.

Modification of furnace shown in patent 597,945, especially designed for the production of cyanides from carbides. The furnace is of the wheel type, carbon electrodes of opposite polarity depending into one side of the annular rim constituting the receptacle. Pipes for supplying nitrogen to the carbide extend outward from the hollow shaft to the rim at different points. A valve in the hollow shaft, or separate valves in the several pipes actuated by fixed tappets, supply nitrogen to the carbide from the time of its formation until it cools below the point at which further absorption will take place.

NEW BOOKS.

Allen, Alfred H. Commercial organic analysis; treatise on the properties, modes of assaying, and proximate analytical examination of the various organic chemicals and products employed in the arts, manufactures, medicine, etc.; with concise methods for the detection and estimation of their impurities, adulterations and products of decomposition. Vol. 1, fourth edition, entirely rewritten. Edited by H. Leffmann and W. A. Davis. Illustrated. Price, $5.00 net Philadelphia: P. Blakiston's Sons & Co.

Armes, Ethel. Story of coal and iron in Alabama. Illustrated. Price, $5. Alabama Chamber of Commerce.

Ball, W. V. Law affecting engineers. 300 pages. Price, $2 net. New York: D. Van Nostrand Company.

Ballinger, W. F., and Emile G. Perrot. Inspector's handbook of reinforced concrete. Price, $1.00. New York: Engineering News.

Bardwell, Fred Leslie, and Elwood B. Speer. Laboratory experiments in inorganic chemistry. Compiled from various sources for the use of students of the Massachusetts Institute of Technology. Price, 75 cents. Boston: F. L. Bardwell.

Bartley, Elias Hudson. Text book of medical and pharmaceutical chemistry., Seventh edition, revised 1909. 749 pages, illustrated. Price, $3. Philadelphia: P. Blakiston's Sons & Co.

Blaine, Robert Gordon. Calculus and its applications Practical treatise for beginners, especially engineering students. Price, $1.50 net. New York: D. Van Nostrand Co.

Breckenridge, Lester Paige, and Paul Diserens. Fuel tests with Illinois coal. (Comp. from tests made by the Technological Branch of the United States Geological Survey, at the St. Louis fuel testing plant, 1904, June 30, 1907). Fifty-four pages, illustrated, tables and diagrams. Urbana, Ill.: University of Illinois.

Cambria Steel Co. Cambria Steel; handbook of information rel. to structural steel manufacture by the Cambria Steel Co., containing useful tables, rules, data and formulae for the use of engineers, architects, builders and mechanics; prepared and compiled by George E. Thackray. Ninth edition. 484 pages. Price, $1.00. New York: Cambria Steel Co.

Durkee, F. W. Experiments in general inorganic chemistry. Second edition, revised. Price, 50 cents. Tufts College, Medford, Mass.

Gillette, Halbert Powers, and R. T. Dana. Cost keeping and management engineering; treatise for engineers, contractors and superintendents engaged in the management of engineering construction. Price, $3.50. Chicago: M. C. Clark Publishing Co.

Gissing, F. T. Commercial peat, its uses and its possibilities. Price, $2.00 net. Philadelphia: J. B. Lippincott Co.

Gregory, R. Arman and H. E. Hadley. Class work of Physics. Price, $1.00 net. New York; Macmillan Company.

Grover, F. Modern gas and oil engine. Fifth edition. Price, $2. New York: Spon & Chamberlain.

Grünwald, Julius. Enameling on iron and steel. Price, $2.00 net. Philadelphia: J. B. Lippincott Co.

Henderson, J. Electrotechnics. (Physical and electrical engineering laboratory manuals.) Price, $1.20. New York, Longmans, Green & Co.

Latta, M. Nisbet. American producer gas practice and industrial gas engineering. Price, $6.00 net. New York: D. Van Nostrand Co.

Lunge, G. Coal, tar and ammonia. Two volumes. Fourth edition. 1210 pages, illustrated. Price, $15.00 net. New York: D. Van Nostrand Co.

Lunge, G. Manufacture of sulphuric acid and alkali; theoretical and practical treatise. Vol. 2: Sulphate of soda, hydrochloric acid, Leblanc soda. Third edition, much enlarged. 1044 pages, illustrated. Price, $15.00 net. New York: D. Van Nostrand Co.

Morgan, J. J. Blast furnace practice. Price, 75 cents net. Philadelphia: J. B. Lippincott Co.

Morsch, Emil. Concrete steel construction (Der Eisenbetonbau); authorized translation from the third (1908) German edition, revised and enlarged by E. P. Goodrich. Price, $5.00. New York: Engineering News.

Munroe, C. E., and Clarence Hall. Primer on explosives for coal miners. 61 pages. (U. S. Dept. of the Interior, U. S. Geological Survey Bull.) U. S. Supt. of Docs.

Normandy, Fk. Sea Water Distillation. Price, $2.00 net Philadelphia: J. B. Lippincott Co.

Sharpe, T. Modern Foundry Practice, including molding, materials used, machinery and appliances, etc. Second edition. Price, $8.00. New York: Spon & Chamberlain.

Shelford, F. Pioneering for engineers; including most suitable camp equipment, rations, medicines, clothing, etc. Price, $1.25. New York: Spon & Chamberlain.

Sudborough, J. J., and J. C. James. Practical organic chemistry. 394 pages, illustrated. Price, $2.00 net. New York: D. Van Nostrand Company.

Stewart, R. Wallace. Elementary text-book of physics. Price, $1.50 net. Philadelphia: J. B. Lippincott Co.

Suplee, H. Harrison. Gas turbine. Progress in the design and construction of turbines operated by gases of combustion. Price, $3.00 net. Philadelphia: J. B. Lippincott Co.

Tutton, A. E. Howard. Crystalline structure and chemical constitution. Price, $1.60 net. New York: Macmillan Company.

Tyrell, H. Gratton. Concrete bridges and culverts for both railroads and highways. Price, $3.00. Chicago: M. C. Clark Publishing Company.

BOOK REVIEWS.

Producer-Gas Fired Furnaces. By **Oscar Nagel.** Ph.D. 8vo., 192 pages, 237 illustrations. Price, $2 net. New York City: The Author (P. O. Box 385).

Intended as a hand-book giving detailed descriptions of these furnaces, it only measurably achieves its object. While the book is in parts commendably written and illustrated, yet other parts are unsatisfactory both in manner of presentation and illustration, while the style, as written English, is faulty throughout. The scientific explanations, where ventured upon, are mostly of doubtful accuracy.

The author is most at home in describing the furnaces used in the lime, cement, brick, ceramic, glass and chemical industries, and in respect to these the book will certainly be found useful; the furnaces used in non-ferrous metal industries are fairly well treated; the furnaces used in the iron and steel industry are poorly handled, the author often showing igno-

rance of the purpose or mode of operation of some particular furnace (e.g., furnace shown in Figs. 77-81).

In describing producers themselves, some blunders occur which decrease the value of the information. The Bildt automatic feed, for instance, is labeled the "Morgan Producer." We cannot consider this chapter as of much value; it is rather a heterogeneous compilation.

Altogether, the subject is neither exhaustively nor equably treated; the book might have been much better. Parts contain useful information which make the book worth while; it is, however, neither scientifically accurate nor otherwise always reliable.

* * *

Modern Coking Practice. By **T. H. Byron** and **J. E. Christopher.** 8vo. 109 illustrations and diagrams, 168 pages. Price 8/6 (in New York, $3.50). London: Crosby, Lockwood & Son.

This is an eminently practical, condensed, well-written work, thoroughly up to date. The authors are chief chemist and submanager, respectively, of the Wigan Coal & Iron Company, and in practical charge of an extensive Semet-Solvay coking plant. The sampling and valuation of the coal and coke, and working up of the by-products, are treated in the same business-like manner as the main subject—the construction and operation of the ovens. The book is recommended to all interested in this subject.

* * *

The Chemistry of Cyanide Solutions. By **J. E. Clennell,** B.Sc. Second edition. 8vo., 202 pages. Price, $2.50 net. New York: McGraw-Hill Book Company.

A second edition of this useful book will be received with pleasure by all who have used the first edition of the work; it is an eminently practical laboratory guide to the metallurgical chemist in charge of a cyanide plant. We would recommend the chemist, however, to use the book as a nucleus about which to accumulate notes of other analytical cyanide methods as they appear from time to time. In that way a complete laboratory guide can be constructed which will put the metallurgist abreast of the best practice of his profession in this line.

Die Herstellung von Hochprocentigem Ferrosilizium im elektrischen Ofen. By Dr. Ing. **Waldemar Pick** and Dr. Ing. **Walter Conrad.** 8vo., 144 pages, 26 illustrations. Price 6.60 marks. (Retail price in New York, $2.15.) Halle a. S., Germany: Wilhelm Knapp.

This monograph on the electric furnace production of high-percentage ferro-silicon is an amplification of the doctor's thesis presented by the authors at the University of Vienna. It contains more detailed and more exact information upon this subject than is to be found anywhere else. The student of electrometallurgy, the electric furnace expert, the manufacturer of ferro-silicon, and the user of the same, will all find the work full of interesting and valuable information.

A short introduction gives the older metallurgical literature on "silicon pig" iron or "glazed pig." A longer chapter describes the recent researches on the silicides of iron, and gives the phase diagram or equilibrium diagram of the various mixtures of iron and silicon, followed by a description of the commercial ferro-silicons.

The spontaneous crumbling of ferro-silicon containing 30 to 65 per cent silicon is next discussed. This is an important topic, because of the decreased market value of such powdered material. Sometimes two samples from the same furnace, with identical analysis, will behave differently, one crumbling and the other not. Their conclusion is that the crumbling is due to a crystalline decomposition, caused primarily by two rapid or too slow setting from the melted condition.

Another interesting subject discussed is the explosiveness of some ferro-silicons, and the poisonous gases given off by them. The explosions are ascribed to gases, like acetylene or silicon hydride, given off by the action of atmospheric moisture and ignited by sparks caused by the attrition of the pieces against each other as the material is moved. The gases are given off particularly by 40 to 60 per cent ferro-silicon, and can be avoided by soaking the material in water or passing steam through it, and then not packing it until it has been thoroughly dried.

Another remedy suggested is to forbid the shipping of 40 to 60 per cent ferro-silicon.

Eight pages are given to the chemical analysis of these alloys, in which the authors give the methods which they have found most reliable.

A sixteen-page chapter describes the various electric-furnace processes which have been proposed and used for making ferro-silicon. The connection of the rise of this industry with the historic "slump" in the calcium carbide business is dwelt upon. The patents of Price and Tone are not very appreciatively mentioned.

There then follow the three most valuable chapters in the book: One of 37 pages on the construction and operation of an electric furnace ferro-silicon plant, another of 8 pages on the theoretical work done in the production of these alloys, and a third of 21 pages on the useful effect and practical efficiency of furnaces in actual operation.

In the chapter on construction and operation of plant, the details are minute and satisfactory; the person following them, however, would need to carefully consider to what extent he might be infringing patented apparatus and methods.

In the calculation of the theoretical work necessary for producing different grades of ferro-silicon, Dr. Henry Noel Potter's determination of the heat of oxidation of silicon, 7595 calories per gram, is taken as the most reliable. With this we agree, but we cannot agree to take Thomsen's value for the heat of oxidation of carbon to monoxide, 2183 calories per gram, which is in error at least 10 per cent; Berthelot's value of 2430 is much more probably correct. The gases escaping from the furnaces are assumed at 700° C, the alloys at 1500° to 2000°, the specific heat of silicon as averaging 0.29, its latent heat of fusion (probably 128 calories) is neglected. With these conditions, a minimum power requirement of 321 kw-days is calculated per ton of silicon. Working with partly un-enclosed arc, the escaping gases are assumed to be at 2000°, and the minimum power requirement is 358 kw-days. For various grades of ferro-silicon the minimum power requirement using metallic iron in the furnace is calculated per ton of product in kw-days as:

	With Enclosed Arcs.	Un-enclosed Arcs.
25 per cent ferro-silicon.....	88 (130)	97 (150)
50 " " " "	165	184

The kw-days given above in parenthesis indicate the minimum power requirement calculated for using iron oxide in the furnace instead of metallic iron.

The investigation of actual furnaces to determine their efficiency gives very interesting results. The net efficiency is only 40 to 50 per cent, the 60 to 50 per cent list being accounted for by radiation and conduction and the vaporization of silica, in the ratio of about 20 per cent to the former and 30 per cent to the latter. The heat required to heat cold SiO_2 to the vaporizing point and vaporize it is taken as 843 calories per gram. One conclusion reached is that at least 2 kg of silicon can be obtained per kw-day, and better results than this have been obtained.

The concluding chapters deal with the influence of the voltage, current used, and impurities present, on the output of silicon and on the purity of the alloys obtained.

As a whole, the book is a highly interesting contribution to electrometallurgical literature, and we congratulate the authors upon their splendid work.

J. W. Richards.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine

Vol. VIII. New York, May 1910 No. 5

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

239 West 39th Street, New York.

Pittsburgh Office, 201 Oliver Building.
Western Office, Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

Pittsburgh and Electrochemistry.

Electrochemical engineering is not a strange or new art in Pittsburgh. On the contrary, the early history of electrochemical industries in this country—Hall's work on aluminium and Acheson's work on carborundum—is intimately connected with the Pittsburgh district. Only after these two pioneer electrochemical industries had been there founded on a commercial scale were they transplanted to the new power center, Niagara Falls, which then grew into the electrochemical center par excellence. Now, however, with electric steel refining furnaces increasing almost daily in importance, it requires no particular flight of fancy to think of Pittsburgh as another coming electrochemical center. But how different such a statement sounds now from what it would have sounded a few years ago. Then iron men would have thought of the electric furnace trying to replace the blast furnace. Now it is universally understood that the big field of the electric furnace in iron and steel metallurgy is as an adjunct to the Bessemer converter and to the open hearth to produce that better steel so urgently needed.

* * *

The American Electrochemical Society has wisely selected Pittsburgh for the place of its annual meeting in May. It can no longer be said that the society enters thereby the enemy's country. Progressive steel men now recognize the helper and friend in the electric furnace man. To reach a perfect mutual understanding of all the various phases of the problem, nothing can be more effective than social intercourse and heart-to-heart talk between both classes of engineers, and for this the convention will offer abundant opportunities. So we look forward expectantly to one of the most successful and pleasant meetings, especially since electrochemists are now returning for the first time as a professional body to the place of their early triumphs. On revient toujours à ses premiers amours.

Oxygen and Nitric Acid from Air.

Mr. Ernest A. LeSueur, who 20 years ago was the pioneer of the diaphragm cell for sodium chloride electrolysis, has contributed to this issue a most interesting article on "commercial oxygen," produced from the atmosphere by a simple mechanical process. The subject attracts just now great attention. If it would be possible to produce "commercial oxygen" cheaply enough, many applications of it in large-scale metallurgical and chemical engineering processes could be worked out. As Mr. LeSueur points out, to be cheap the method should be a mechanical or physical rather than a chemical one; further, it should not be necessary to produce pure oxygen. If an atmosphere enriched in oxygen compared with the ordinary atmosphere is sufficient, he claims it can be produced at a very reasonable figure by a sort of turbine or "steam engine."

* * *

In this connection attention may be called to an abstract of a patent of Mr. Henry Howard, also given in this issue, for the continuous production of nitric acid from air. In a very clever

way the machinery is so designed as to fulfill the desiderata of that theory according to which the oxidation of the nitrogen is a purely thermal phenomenon. First, compression, and, by electric discharges, establishment of a gas mixture comparatively rich in nitrogen oxides, and then an exceedingly quick cooling of the mixture so as to "freeze" the equilibrium corresponding to the higher temperature and prevent the dissociation of the nitrogen oxide. This cooling effect is obtained by sudden expansion of the gas mixture while performing work in an engine or turbine. Mr LeSueur's article and Mr. Howard's patent are interesting examples of the novel application of mechanical engineering principles in chemistry.

Friedrich Kohlrausch.

In Friedrich Kohlrausch, Germany has lost one of its most prominent and influential physicists, a past-president of the Physikalisch-Technische Reichsanstalt and the one man who has done more than anyone else to cultivate experimental laboratory work in physics in German universities. As to his research work along manifold lines, attention may be called here only to his very extended and minutely accurate investigation of the electric conductivity of salt solutions at varying concentrations, which, taken together with Hittorf's determination of transference numbers, enabled him to establish the law of the "independent migration of ions" for infinitely dilute solutions. Qualitatively at least, this was the first statement of the electrolytic dissociation theory. What has been added later is Arrhenius' method of determining by different methods the degree of dissociation in solutions which are not infinitely dilute and the great generalization of the theory by numerous investigators whereby it became possible to apply it to many problems of the theory of solutions and of general chemistry.

The Passing of the Argo Smelter in Denver.

The last days of March witnessed the drawing of the fires from the furnaces at the smelting plant of the Boston & Colorado Smelting Company at Denver. The Argo smelter, as the plant was commonly known, has been one of the most interesting and important factors in Western metallurgy for almost 40 years. Originally established at Black Hawk, 30 miles from Denver, at a time when the rich surface free-milling ores of that famous camp had given place to sulphides, the Argo smelter played a leading part in the fortunes of the miners who were discouraged over their rapidly diminishing gold recoveries from ore known to contain high values. The leading spirit in establishing the smelter was Nathaniel P. Hill, at that time a young Eastern college professor. The process used resulted in the production of a rich copper matte which was shipped to Swansea for refining. Later Mr. Richard Pearce introduced the Ziervogel process for recovering the silver, and introduced a method for treating the residues for gold which was kept secret for almost 40 years. When finally disclosed it was found to be simple, and a number of metallurgists confessed to having guessed the principles involved some years before their disclosure. The gold was concentrated in copper bottoms which were subsequently granulated and smelted in a reverberatory furnace with iron pyrites. Successive meltings and granulations with final treatment in the refinery in crucibles yielded a bullion 950 fine in gold.

This system of smelting and refining, using copper as a base, was continued to the end, although lead smelting developed far beyond the possibilities of copper smelting in Colorado. In 1906 the Argo refinery was destroyed by fire and since that time the matte has been sold to the American Smelting & Refining Company. The diminishing fortunes of the Argo plant were coincident with the discovery of rich lead ores and the genesis of lead smelting in Colorado. Copper ores have never been abundant in that State, and it has always been possible to handle them in lead smelting plants, producing a low-grade matte which was subsequently concentrated to a grade suitable for refining in the converter. The Argo company at one time established a second plant at Alma, Col., but it was not profitably operated and was finally abandoned. It is an interesting speculation to consider what would have been the effect on the lead smelting industry of the West had the Argo company entered the lead smelting field instead of sticking to its own process, which finally became antiquated. The ingenuity of its metallurgists and the prestige of its financial backers should have made it a formidable factor in present-day developments. The history of the company shows it to have been very successful, and it retires with the good will of many miners who had dealings with it.

Pittsburg's Supremacy in Iron and Steel.

It is only among those who are unaccustomed to think in quantities that the notion has been entertained that Pittsburg loses any material part of her prestige as an iron and steel producing center by the building of the steel plant at Gary, Ind. The Gary plant exemplifies an important economic principle, but by no means a new one. Nearly 20 years ago it was common talk in the industry that a location on the Great Lakes had an advantage over the remainder of the Central West, because it was better for the fuel to go to the ore than the ore to the fuel, but instead of a general exodus only a few stragglers have wended their way to a lake site. The Johnson Company moved from Johnstown, Pa., to Lorain, Ohio, making its first steel at the new site April 1, 1895, but owing to financial stress did not obtain the real benefit of the lake site for more than four years, since it was not until July 5, 1899, that the company made pig iron at Lorain. A few years later the Lackawanna Iron & Steel Company packed up its goods at Scranton, Pa., and moved to Buffalo. The Gary plant, at the south end of Lake Michigan, is, of course, different in that it does not in any sense represent a removal, for the United States Steel Corporation has clearly had no intention of moving any equipment or transferring any trade. The Gary plant is built from the ground up, with fresh capital, and its object is to take care of the increased requirements of the Western market.

* * *

The Gary plans, as outlined in the steel corporation's report for 1907, comprised eight blast furnaces and 56 60-ton open hearth furnaces, the blast furnaces being rated at 450 tons per day each, and the 56 open-hearth furnaces at 225,000 tons of ingots per month. This much was authorized at the time, and the statement was further made that an increase in the blast furnaces to 16 was ultimately contemplated, with a corresponding increase in the open-hearth and other equipment. In either case there would have been a large preponderance of steel mak-

ing over blast-furnace capacity. Apparently the plans have since been modified, for the present status of the work is that of eight blast furnaces completed, with six in blast and 28 open-hearth furnaces completed and in operation, with 14 to be completed this summer, eight blast furnaces and 42 open-hearth furnaces being expected to balance. It does not seem probable that the project will be expanded beyond these limits for some time. The function of Gary is to make steel by the most modern and approved methods, rather than to make an enormously large tonnage. The eight furnaces may be rated at 1,200,000 tons of pig iron annually, the steel ingot production being larger, through the reuse of scrap, while the finished steel output will doubtless be approximately commensurate with the pig iron tonnage.

* * *

From a tonnage standpoint, Pittsburg need not consider such an operation as presenting serious rivalry. One can arrive at Pittsburg's tonnage potentialities better by a study of what has been accomplished than by a mere survey of rated capacities. To do this it is necessary to go back to 1906, the last year of full employment, and then allow for new construction since that time. This, by the way, will show quite forcibly that Pittsburg has not stopped growing. Statistics of the production of Allegheny County, of which Pittsburg is the county seat, are given for 1906 as follows by the American Iron & Steel Association:

	Gross tons.
Pig iron	5,702,721
Bessemer steel	3,255,064
Open-hearth steel	3,799,907
Other steel	50,530
All steel	7,105,501
Rails	851,419
Structural shapes	1,054,747
Plates and sheets	1,300 873
All rolled products	5,686,017

The Mahoning and Shenango valleys, midway between Pittsburg and Lake Erie, and the Wheeling district, as well as various scattered plants in Western Pennsylvania, might perhaps be included with Pittsburg, but drawing a strict line we include with Allegheny County only a few plants just outside the county and distant less than 30 miles as the crow flies from the heart of Pittsburg. Thus we add to the above tonnage an allowance for the Midland and the two Donora furnaces, about 450,000 tons of pig iron annually. Since 1906 there have been built and put in operation within this circumscribed district: In 1907, two Carrie and one McKeesport furnaces; in 1909, two Dusquesne and one Aliquippa; in 1910, two Aliquippa, these eight furnaces having a rated capacity of 1,370,000 tons a year. Altogether, then, the present pig iron capacity of the immediate Pittsburg district is fully 7,500,000 tons a year, more than six times the prospective capacity of the Gary plant as at present outlined.

* * *

In steel capacity there is an increase since 1906. The Bessemer department at Duquesne, two 10-ton vessels, has been dismantled, but in place are 18 open-hearth furnaces with greater capacity; at Homestead there is additional open-hearth capacity, and at Aliquippa the Jones & Laughlin Steel Company is completing four 200-ton Talbot furnaces. With minor improvements at other plants, and considering the steel capacity at Vandergrift, Butler and Donora, just outside the county, the prospective steel ingot capacity is well in excess of 8,000,000 tons annually. With 7,500,000 tons of pig iron capacity, the Pittsburg district makes only about a quarter-million tons of merchant pig iron a year. It is not a center for the manufacture of the finer products of the foundry, nor, indeed, does it surpass other districts so much in the finer forms of steel as it does in tonnage. There is room for Pittsburg to grow along these lines, as the necessity is reduced for it to grow in the production of the heavy forms of steel.

Refractory Brick.

The subject of refractories is of immense importance for metallurgical and chemical works. But the knowledge of this subject is scattered and illusive or at least indefinite. By their contact with the whole of chemical and metallurgical industries the makers of firebrick have acquired some practical data of undoubted general value on the relation between methods of manufacture and properties of firebrick, while chemists and metallurgists in special fields have valuable and definite ideas on what kind of special refractories they want or need. But the trouble seems to be that there is not yet the right co-operation or understanding between the manufacturer and consumer of refractory brick. That a refractory brick may be excellent for one purpose and wholly unsatisfactory for another goes without saying. An acid brick is destroyed by a basic charge or slag. But besides the chemical nature of the reaction, the purely physical factors are of equal importance. The consumer should know the maximum temperature which his brick has to stand, and the firebrick manufacturer should adjust his baking process accordingly so as to produce a brick that will not shrink at the highest temperature in use. To indicate how contradictory the requirements are in different cases, we may simply mention that in most cases firebrick is expected to be a poor heat conductor in order to reduce the heat loss, while in other cases—in zinc retorts, in muffle roasting, crucible melting, etc.—the refractory is expected to transport the heat from the outside to the inside with high efficiency. It seems that a discussion of the subject of refractories from the standpoint of both the consumer and producer should do much good for both parties concerned. It is with pleasure that we call attention to an interesting article on defects in refractory brick and their causes, contributed to this issue by Mr. Gilbert Rigg, in charge of the experimental work of the New Jersey Zinc Company. It is the result of a large number of studies and tests and is contributed in the hope of starting a discussion on this subject. For this purpose and in the hope of doing something useful we place our columns gladly at the disposal of both users and makers of refractory brick.

Irregularities of Blast-Furnace Running.

Our January issue contained an article on regularity of blast-furnace operation, by Dr. Joseph W. Richards, and in the present issue will be found an article, more or less supplementary to the former one, on the chief irregularities of blast-furnace running by Mr. Edward R. Cook, of the Warwick Iron Company, written from the blast-furnace manager's standpoint.

That these two authorities should agree on the main points under discussion is highly satisfactory from the standpoint of blast-furnace literature; that they should lay the chief emphasis on different phases of the problem is perfectly natural and no less instructive than their points of agreement. In brief, Dr. Richards assumes a furnace in good running order, not near the close of a campaign, and discusses the factors of regularity in its running such as are concerned with its immediate management and treatment. On the other hand, Mr. Cook starts with the tacit assumption that all these factors are inferior in importance to combating those secular changes which mark declines in output steadily operating through months of running and which finally compel the furnace to go "out of blast." Mr. Cook very aptly says: "Take a blast furnace built on proper lines and anybody can run it; take one built improperly and no one can run it." Dr. Richards' discussion applies, therefore, to the best and most regular running of a furnace assumed to be built properly; Mr. Cook's mainly to the irregularities and difficulties met in a furnace built improperly, causing secular changes which finally stop the furnace.

* * *

Both discussions are, therefore, valuable, and we do not hesitate to designate Mr. Cook's as the more fundamental, because it is certainly imperative to have, first, a furnace capable of being kept "in blast" before it becomes worth while to discuss how to run it most regularly and most efficiently. Mr. Cook has discussed the great fundamental difficulty of keeping the blast furnace in operation; Dr. Richards the fine points and finishing touches, or refinements concerned in its steady operation at highest efficiency. Some of Mr. Cook's statements will hardly pass the scrutiny of the blast-furnace profession unchallenged. The statement that no one knows how to build the blast furnace right should provoke discussion. His statement that the three largest producing blast furnaces in the United States, in 1909, were three dry-blast furnaces, certainly proves the very great importance and value of the items of regularity discussed by Dr. Richards. In fact, we cannot but regard the questions raised as "open" questions, and their further discussion by technicians and theorists is likely to prove profitable all around.

Bessemer Roasting.

Evolution of technical terms is coincident with the changes in practice, and final usage is usually dictated only by a full understanding of the principles of a method or process. As long as the latter is in a transitional stage, the descriptive terms used are likely to be numerous, local in their origin and meaning, and not wholly satisfactory. The developments of the past few years in the practice of roasting sulphide ores have given rise to a number of terms, no one of which seems wholly adequate to express concisely the principles involved and the result obtained. Various terms such as sintering, pot roasting, layer roasting, blast roasting, lime roasting, etc., have been proposed and used. An analysis of these terms will show that each of them has some special significance, referring to the mechanical device used, the nature of the mixture to be roasted, or the general result obtained, but none of them can be considered a generic term complying with the conditions mentioned, so that it is worth while to look for a better one.

A recent metallurgical writer has suggested the use of the term "Bessemer roasting," as fulfilling all the conditions. The Bessemer process implies the use of a blast of air to effect certain chemical changes without the use of extraneous fuel. In steel making the Bessemer process is based upon the heat evolved by the oxidation of certain elements in pig iron. In "Bessemerizing" copper matte we have similar conditions and results, applying a blast of air to oxidize sulphur and iron and to liberate copper. Finally the analogy is apparent in what it is proposed to call Bessemer roasting, for in that process we resort to a blast of air to oxidize the sulphur, and the process is carried on with the fuel contained in the ore itself. The suggested term is properly descriptive from a metallurgical point of view. It is independent of the details of the mechanical application of the process, which, indeed, are the most unsettled features of it. Roasting in pots was an early application, and only a short time ago it appeared that roasting in thin layers would supersede the pot process, but that has not yet come to pass. The term "lime roasting" is no longer tenable, since it lays stress on a feature now known to be unessential. Finally, sintering can be accomplished in a variety of ways and furnaces, and the term has no reference to the Bessemer feature of the roasting process as now carried out. On the whole it seems as though the term "Bessemer roasting" is the most acceptable that has been proposed, and we are glad to endorse it and bespeak for it general usage.

Pittsburgh and By-Product Coking.

It would appear that the iron and steel industry has experienced sufficient expansion in tonnage capacity to cover the requirements of the market for a time and is destined to devote its energies chiefly to the introduction of economies and improvement of product. In the last dozen years three periods of high pressure have alternated with periods of depression. The spectacular boom of 1899 was followed by a sharp and short readjustment in 1900; the next period of high pressure lasted longer, and was followed by the depression extending from late in 1903 to late in 1904, this giving way to three years of high pressure followed by a depression of a year and a half. Each period of high pressure caused plans to be adopted for new erection, much of the new capacity not becoming effective until the pressure for material had subsided. The next period of high pressure would show the new capacity to be needed, and would give rise to a fresh burst of new erection. The longer the period of high pressure, the greater the amount of new erection undertaken, and thus it came about that in the most recent period of high pressure the crop of new blast furnaces and steel works was by far the largest of all. The depression is past, the new erection is not all completed, yet existing capacity is not fully engaged. In other revivals it required but a few months to take up all the slack and produce a position in which mills were falling farther and farther behind in their deliveries.

* * *

The iron and steel industry is always improving its methods and appliances, but the rate of progress varies from time to time. We do not assert that if it were possible to list all the improvements made in the past quarter century it would not be found that more improvements were introduced in periods of extreme prosperity than in periods of relative depression, but

if so the showing would be made so by there being much more new erection in periods of prosperity than in periods of adversity. Relative to the amount of money spent, the greatest progress is undoubtedly made when profits are small. Nothing could be more natural. When existing capacity is taxed and producers are falling behind in deliveries it is justifiable in new erection to build as others have built before; when existing capacity is not fully engaged it is necessary to justify the new erection by improvements over existing practice. In these circumstances the next few years in the iron and steel industry promise to constitute a period of improvement in methods and appliances. Along these lines by-product coking looms large. In our March number we pointed out that the development of the large gas engine greatly increased the feasibility of by-product coking by furnishing a new and unlimited field of usefulness for the gas, and we do not wish here to traverse any of that ground again. Rather, we take as our theme the Pittsburgh district as a locus for by-product coking. The suggestion as to the unwisdom of "carrying coals to New Castle" may arise in the minds of some of our readers, but let us look into the matter a little. The Pittsburgh district is one of the greatest consumers of power in the world, and most naturally, for once Pittsburgh was only the junction of two rivers surrounded by forests and the industries were attracted chiefly by cheap fuel; naturally they were industries which require a great deal of it. Pittsburgh was the home of aluminium manufacture until the Niagara Falls power became available.

* * *

Pittsburgh, it may be said, is a natural gas center; hence, why try to make there the much poorer gas which by-product coking yields? Let us see. From a natural gas standpoint the State of Pennsylvania is practically the Pittsburgh district. The Geological Survey reports show a rapid increase in Pennsylvania's natural gas production, until 1904, since which year the value has been almost stationary, and we know perfectly well that the quantity must therefore have been decreasing, since values per 1000 ft. have been steadily increasing. Statistics of quantity are available only for 1907 and 1908. They are as follows for Pennsylvania, in thousands of cubic feet:

	1907.	1908.
Production	135,516,015	130,476,237
Consumption	164,541,179	147,790,097

The decreased consumption in 1908 was, of course, due to the industrial depression. Pennsylvania, as a matter of fact, imports a great deal of natural gas from West Virginia, and is destined to import more and more, if no substitute is found. Fortunately for our purpose, the Geological Survey has divided the consumption for domestic and industrial purposes, and in view of the industrial depression we cite only the figures for 1907 as follows:

	1000 cu. ft.	Value—Cents per 1000 cu. ft.
Domestic	44,840,748	24.2
Industrial	119,700,431	10.1

Inasmuch as the domestic consumption in Pittsburgh is steadily increasing and as West Virginia gas can be piped to many towns for domestic consumption, it would be absurd to expect that the gas would continually be sold for industrial purposes when it will bring more than twice as much if sold for domestic consumption. Indeed, a large part of the gas used for industrial purposes is produced by the manufacturers, who are not in the business of distributing for domestic consumption. Year by year the cost of finding and developing new wells increases, so that the use of natural gas for industrial purposes in the Pittsburgh district is necessarily decadent.

* * *

An oblique view is frequently taken of the hardiness, both of Connellsville coking coal and of Lake Superior iron ore. In both cases the reputation of the region was made by the best of the deposits, but in summaries of the "life" of the region the conception seems to be the product of the quality of the best by the quantity of the total. Much of the best Connellsville coking coal is gone, just as much of the best Lake Superior ore is gone. Pittsburgh industries can use an almost unlimited amount of by-product gas, and the coke requirements are equally large. Connellsville coke takes a freight rate to Pittsburgh of no less than 75 cents per ton of 2000 lb. for a haul perhaps averaging 50 miles. When blast furnaces were put in operation at Aliquippa only 20.5 miles below Pittsburgh, a rate of 99 cents was made on Connellsville coke, 24 cents being added for 20.5 miles additional haul. There is coal everywhere about Pittsburgh, most of it adapted to by-product coking, and in many cases there need be no freight charge at all. In other cases the rate would be very low, compared with the preposterous rate on Connellsville coke. There would even be an advantage in making by-product coke at Pittsburgh for consumption elsewhere, since Pittsburgh could use the gas and allow the coke to go. In cases in which the coal had to be transported to the by-product ovens a low freight rate could undoubtedly be obtained, on the principle well recognized by the railroads of permitting manufacture in transit. Observing this principle, the railroads are at the present time making very low rates on Connellsville coal shipped for coking to beehive ovens whose coal seams are worked out.

* * *

While the railroads maintain very high rates on Connellsville coke, they could be counted upon to make the lowest possible rates in connection with the establishment of by-product ovens, for the railroads are committed to the fostering of this industry in order to increase the supply of creosote obtained from coal, since they need the material for tie preservation and expect to require very large quantities. In the report of the special committee on "Conservation" presented to the annual meeting at Chicago, last March, of the American Railway Engineering and Maintenance of Way Association, one of the recommendations was: "That efforts be made to secure such improvements and economies in the construction and operation of by-product coke ovens as will lead to their general substitution for the beehive type." The immediate Pittsburgh district promises to consume regularly approximately 8,000,000 tons of coke, chiefly in blast furnaces. Surely there is reason to expect that ultimately most of the coke will be made in by-product ovens, the gas being used for various industrial purposes. Of course, the blast furnace is itself a gas producer and it is claimed that blast-furnace gas is sufficient to furnish all the power necessary to finish steel in the heavier rolled forms. There remains, however, the heating of the steel and as electric steel refining grows, employment will be furnished for all the gas from both coke oven and blast furnace.

Pittsburgh Meeting of the American Electrochemical Society.

The seventeenth general meeting of the American Electrochemical Society will be held in Pittsburgh from May 4 to 7 (that is, Wednesday to Saturday of the first week in May). Hotel headquarters will be at the Fort Pitt Hotel, quite near the Union Station. The registration of members and guests will begin at the Fort Pitt Hotel after 12 m. Wednesday, May 4. Tickets for the all-day Friday excursion and the Friday evening dinner should be obtained from the registrar when registering.

The program is as follows:

Wednesday afternoon, May 4. A visit, starting from the Fort Pitt Hotel, at 1:30 p. m., will be made to the technological testing plant of the U. S. Geological Survey. This is perhaps the largest Government testing plant in the world and its inspection will be of the highest interest to the scientific technologist, especially as the management is arranging special tests and exhibitions of particular interest to the visitors.

In the evening at 8:30 p. m. there will be an informal reception in the English Room of the Fort Pitt Hotel by the officers of the society and the local committee to the visiting members, ladies and guests.

Thursday morning, May 5. The annual business meeting of the society will be held at 10 a. m. in the Convention Hall of the Fort Pitt Hotel, where the result of the annual election of officers will be announced and the report of the board of directors will be presented.

This is to be followed by a professional session at which the following papers will be read and discussed:

Determination of the constants of materials for furnace electrodes. By Carl Hering.

Empirical laws of furnace electrodes. By Carl Hering.

On Hering's alleged laws of electrode losses in electric furnaces. By C. J. Reed.

A study in furnace conductors for heavy alternating currents. By K. C. Randall.

A new electric steel furnace. By A. L. Queneau.

On the presence and influence of gases in steel. By P. L. T. Héroult.

Thursday afternoon, May 5. Excursions and visits to the following plants have been arranged for the afternoon, all proceeding from the Fort Pitt Hotel, after lunch, each under the direction of one or more guides familiar with the plants to be visited.

Pennsylvania Smelting Company, Carnegie, Pa. (Smelting of lead silver ores in blast-furnace, refining and desilverizing base bullion, cupellation of silver, etc.)

Park Steel Works of Crucible Steel Company of America. (Puddling furnaces producing muck-bar, open-hearth furnaces producing basic open-hearth steel, crucible furnaces producing high-grade tool steels.)

Jones & Laughlin Steel Company. (Bessemer steel process, basic open-hearth process, Talbot continuous process in tilting furnaces. Rolling of merchant bars, structural shapes, plates, sheet bars, cold-rolled shafting, etc.)

Isabella Furnaces of Carnegie Steel Company, Sharpsburg. (Modern iron blast furnaces equipped with Gayley's original plant for drying the blast.)

Universal Cement Works. (Manufacture of cement from granulated blast-furnace slag.)

Pittsburgh Reinforced Brazing & Machine Company. (Brazing and repairing broken castings by special methods. Oxy-acetylene welding of heavy and light work.)

Nernst Lamp Company. (Manufacture of commercial Nernst lamps.)

Thursday evening, 8 o'clock. A session will be held in the Convention Hall of the Fort Pitt Hotel.

The retiring president, Dr. J. H. Baekeland, will deliver his presidential address on "Science and Industry," whereupon the following papers will be read and discussed:

Possibilities of cheap power in the Pittsburgh district. By F. Crabtree.

Induction furnace progress. By T. Rowlands.

Ductile tungsten and molybdenum. By C. C. Fink.

A new process for the treating of cobalt-nickel ores rich in silver and arsenic, by combined melting and electrolytic operation. By C. C. Cito.

Evolution and present status of the dry cell. By D. L. Ordway.

A new radiation pyrometer. By C. E. Foster.

Friday, May 6. All-day excursion, leaving Union Station at 8:20 a. m. on special train. Lunch will be served on the train, and the following plants visited in the order given, returning to Pittsburgh about 5:30 p. m.:

Allegheny Plate Glass Works, Glassmere.

Westinghouse Electric Works, East Pittsburgh.

Westinghouse Machine Works, East Pittsburgh.

Firth-Stirling Works, Demmler (Héroult electric steel furnace in operation).

Carnegie Steel Works, Homestead.

Tickets for the excursion may be obtained from the registrar at a cost of $1.50.

Friday evening, at 7 o'clock, an informal subscription dinner will be held at the Fort Pitt Hotel. Ladies are particularly invited.

Saturday morning, May 7, 9 o'clock, a professional session will be held in the Engineering Building of the University of Pittsburgh. The following papers will be read and discussed:

On the separation of oil from condenser water by electrolysis. By H. M. Goodwin.

A new method for electrolytic winning and refining of metals. By E. M. Chance.

An electrolytic method for the reduction of casiterite. By W. O. Snelling.

Refining of tin dross in an electric furnace. By R. S. Wile.

The conductivity and electrolysis of cuprous chloride solutions. By M. deKay Thompson.

The electrolytic reduction of nitric acid (third paper). By H. E. Patten and W. J. McCaughey.

The effect of moisture and of solutions upon the electrical conductivity of soils. By R. E. O. Davis.

The electrochemical potentials of calcium-aluminium alloys. By Jas. Breckenridge.

A rotating graphite anode. By J. W. Turrentine.

Comparison of rapid electrochemical methods. Part 1.—The Determination of Copper. By F. C. Frary and A. B. Peterson.

The electrolytic deposition of platinum—II. By Wm. J. McCaughey and H. E. Patten.

The use of perchloric acid in metal-plating baths. By C. F. Mathers.

The Whiting electrolytic cell for the production of caustic alkali and chlorine. By Jasper Whiting.

The Townsend cell; its behavior under various current densities. By H. K. Richardson and R. L. Patterson.

Lunch will be taken in the Hotel Schenley.

Saturday afternoon, 2:30, a general public meeting will be held in Carnegie Music Hall, when an illustrated address on the present status of the electrochemical industries will be delivered by Dr. J. W. Richards, secretary of the American Electrochemical Society.

This will be followed by Dr. John A. Brashear on the advantages of Pittsburgh as an electrochemical center.

Finally, an address on the conservation and utilization of natural sources of power will be made by Mr. John H. Finney.

This meeting may be conveniently followed by visits to the Carnegie Institution and Museum, Carnegie Technical Schools,

University of Pittsburgh, and other points of interest in the vicinity.

For the evening arrangements will be made for a social gathering of members and guests who do not leave by the early evening trains.

A ladies' committee will take care of the entertainment of visiting ladies. Ladies are invited to attend the session of the society on Thursday morning and evening and Saturday morning, and are specially invited to the general public meeting in Carnegie Music Hall on Saturday afternoon. Ladies are also invited to attend the visit to the U. S. Testing Plant on Wednesday afternoon and any of the visits scheduled for Thursday afternoon.

Ladies are particularly invited to be present at the informal reception on Wednesday evening, at the informal dinner on Friday evening and also to the lunch at Saturday noon.

Ladies are not invited to accompany the all-day excursion on Friday; on this day the Ladies' Committee will provide a pleasurable program consisting of automobile rides, visits to art galleries, lunch, etc.

San Francisco Meeting of the American Chemical Society.

The summer meeting of the American Chemical Society, to be held in San Francisco from July 12 to 15, 1910, promises to be one of the pleasantest outings ever enjoyed by the members of the society.

A special train made up of the Santa Fé's finest equipment will leave Chicago on the evening of July 4, arriving at Colorado Springs on the morning of July 6. About six hours will be allowed for a trip to Manitou, the Garden of the Gods or to the top of Pike's Peak. Leaving about 1 o'clock the train will reach Adamana on July 7 and a half day will be spent in a visit to the Petrified Forests, two of which and possibly three may be examined. Leaving Adamana that night the party will arrive at the Grand Canyon of the Colorado on the morning of July 8, where the day will be spent. Leaving the Grand Canyon that evening the train will arrive at Redlands and Riverside, Cal., the following afternoon and about two hours and a half will be given to the semi-tropical scenery of each of these two cities.

Sunday, July 10, will be spent at Los Angeles, leaving there in the evening and arriving at Lang, Cal., on the following morning. At Lang the borax mines will be visited on invitation of Mr. S. T. Mather, of the Thorkildsen-Mather Company, where the party will be their guests until about 1:30 o'clock, when the train will leave for Santa Barbara, giving us about five hours in that unequalled seaside resort. During the night the train will leave for San Francisco via the coast route of the Southern Pacific, probably reaching our destination about 12 o'clock of the 12th.

The meeting will follow and entertainment by the California Section. The tentative program for the entertainment includes: First, a steamer trip around the bay and out through the Golden Gate; second, a trip to the top of Mt. Tamalpias and to the Muir Woods, the first giving an extensive view of the ocean, the bay and the surrounding mountains and hills, while the second contains fine specimens of the coast redwood (*sequoia sempervirons*); third, an excursion on the Ocean Shore Railway to Pescadero with a possible return via the Santa Clara Valley; fourth, an excursion to the vineyards and wineries of the Italian-Swiss colonies in Sonoma County; fifth, a visit to the University of California at Berkeley; sixth, a visit to Stanford University with a possible automobile trip through the orchards of the Santa Clara Valley; seventh, a camping-out trip for one night and parts of two days into the Big Basin, the State Park, where some of the biggest redwoods are to be seen; also it is hoped to visit some of the local manufacturing plants.

Following the meeting the party will dissolve as a whole, returning as they desire, either via the smelters in Utah and Colorado, via the beautiful scenery of the Canadian Pacific, or via the National Yellowstone Park.

Unusually low rates have been obtained from Chicago; namely, $62.50 for the round trip from that city with $15 extra if the party returns via the northern routes. There will be $6.50 extra railway fare on the side trip to the Grand Canyon. The berth rate from Chicago to San Francisco will be $14, with an additional charge for the four extra days in transit in lieu of hotel expenses, as the Pullmans will be used throughout the trip. This additional charge will approximate $7 on the berth rate.

The Puget Sound Section are hoping that a considerable number of the members may decide to return via Seattle.

In view of the efforts that are being made by the California members and of the unusual attractions of the trip, it is hoped that a special effort will be made by Eastern members to be present at the meeting. Reservations for the special train will be made in the order of their receipt. Any members of allied societies going West at this time who may wish to share in the privileges of the special train should address the secretary, Dr. Charles L. Parsons, New Hampshire College, Durham, N. H.

Successor to Dr. Chandler Appointed.

The trustees of Columbia University have announced important changes in the department of chemistry made necessary by the announced retirement of Prof. Charles F. Chandler. The administrative duties of the department will be assumed by Dr. Marston T. Bogert and a new chair of industrial chemistry has been created to be filled by Mr. Milton C. Whitaker. Dr. Bogert, a past-president of the American Chemical Society, has been associated with Dr. Chandler as professor of organic chemistry, and will now be administrative head of the department. Mr. Whitaker has been superintendent of the Welsbach Company's works at Gloucester, N. J. In 1897 he graduated from the University of Colorado and entered Columbia University as a graduate student, where he engaged in research work in the department of chemistry until 1902, when he entered the employ of the Welsbach Company. Mr. Whitaker's work in the department will begin next school year. The trustees also announce the acceptance of the fund raised by the alumni of the University to establish a lectureship in honor of Dr. Chandler.

Enlargement of Ingot Iron Works.

Elsewhere in this issue will be found an article by Mr. James A. Aupperle, chief engineer of the American Rolling Mill Company, of Middletown, Ohio, on their American ingot iron. In this connection the following notes on considerable enlargements of the works of this company should be of interest.

The American Rolling Mill Company is erecting a new plant at Middletown, Ohio, the cost of which when completed is estimated at $3,300,000. It is on a lot of 475 acres, one mile east of the present 50-acre plant, and connected by private right-of-war. The P. R. R., Big Four, and C. H. & D. offer excellent shipping facilities.

The work being done at present is largely grading, and a couple of steam shovels are busily engaged making the change of some seven feet, which is the average for the entire plot.

One of the unusual features of the new plant is the elimination of the narrow-gauge "dinkey" service. All trackages throughout will be of standard gauge.

The plans of the proposed equipment call for four 65-ton, open-hearth furnaces; one, 40" blooming mill; one 24" billet mill; two jobbing mills; eight sheet mills, together with a complete cold rolling department for the manufacture of uniform color sheets. For the galvanized sheets, eight pots will be provided, the hot process, of course, being employed.

At present the company buys pig iron, but the ultimate plan calls for the erection of blast furnaces to furnish all necessary stock.

The entire new plant, with the exception of the blooming and billet mills, will be electrically driven, and Westinghouse apparatus is to be installed throughout.

Three turbo-generators, each of 2150 kilovolt-ampere capacity (1500 kilowatts at 70 per cent. power factor), will furnish the power. The turbines are high-pressure and low-pressure, the former taking steam direct from the boiler plant and the latter using the exhaust from the engines on the blooming and billet mills. In case of shortage in the latter, automatic interconnection of the units permits the admission of live steam direct to the low-pressure turbine. This device also gives a very great overload capacity. The low-pressure turbine installation offers obvious advantages, as the power for the largest rolling mill engines can be obtained at a very high total thermal efficiency.

The sheet and jobbing mills are to be driven, respectively, by one 1500-hp and one 1000-hp alternating-current motor, each operated at 2200 volts and 25 cycles, the current coming direct from the alternators.

The cranes and tables will all be operated by direct current, the well-known Westinghouse "mill-type" motors being used and current furnished at 250 volts by two 750-kw rotary converters.

Shears, conveyors, and such other machinery as is in continuous operation will be driven by alternating-current, 220-volt induction motors.

The electrical installation is in charge of Mr. W. J. Beck. It is hoped to have the new plant running in less than a year, or about February, 1911.

New Laboratory.—The care and rigid inspection necessary in the manufacture of "American ingot iron" has resulted in the erection, now under way, of a new laboratory of research engineering.

This building is 40 x 60 ft., and will be provided with the most modern equipment on the market for conducting electrical and physical tests, as well as complete apparatus for the chemical and microscopical examination of irons and steels.

One section of the basement will be used for making accelerated corrosion tests, in which samples of iron will alternately be subjected to salt water and heated air. The automatic device for accomplishing this, which has been designed by Mr. J. A. Aupperle, chief engineer, consists essentially of a slowly revolving Ferris wheel about seven feet in diameter. A companion wheel will dip into fresh water.

Another feature of the corrosion investigations will be the carbonic-acid moisture tests in which a measured volume of illuminating gas is burned to produce moisture and CO_2 as suggested by Professor Charles F. Burgess, of the University of Wisconsin.

We hope to be able to give a more detailed description of the laboratory later. With its equipment it will cost $40,000, and is to be ready for service about August 1, 1910.

A New By-Product Coke Oven Plant.

The Bethlehem Steel Company has recently closed a contract through Messrs. Frederick J. Mayer and David B. Carse, of New York, with the Didier-March Company, a concern whose stock is largely held in Germany for the construction of a by-product coke oven plant which will be capable of coking about 4300 tons of coal per day, and an ultimate capacity of about twice this amount.

It is understood that the ovens used will be of the double underflue type, so arranged that there will be no reversing of the direction of the gases or the products of combustion. The ovens will have a capacity of about 10 tons each, there being in the first installation four batteries of 75 ovens each, or a total of 300 ovens.

This contract was made in the interest of the Berlin Anhaltische Maschinenbau Aktien Gesellschaft of Berlin, Germany, and the Stettiner Chamotte Fabrik Aktien Gesellschaft of Stettin, Germany. These concerns are the largest manufacturers in Europe of gas works, transmission machinery, by-product apparatus, and refractory materials. The Bethlehem plant will, therefore, be of the most modern type, with the latest machinery for the handling of all the materials.

It is understood that there will be installed a new process for the direct recovery of ammonia, a large briquetting plant, and apparatus for the distillation of tar. The coal storage will take care of 30 days' consumption at the rate of 8600 gross tons of coal per day, or sufficient for the doubling of the plant, which will soon be built.

It is reported that the interests building this plant are now active competitors for by-product plants in this country.

The United States vs. Anaconda Copper Mining Co.

Apropos the smelter fume problem which has occupied the attention of smelters and farmers for several years, it is interesting to note that the Federal Government has taken a hand for the purpose of protecting national forest reserves from alleged damage, and has sued the Anaconda Copper Mining Company, praying for an injunction to close the Washoe smelter in Montana. The Government's intention is to force the company to make such disposition of sulphur and arsenic fumes as shall render them innocuous. Experts for the Government claim that the outcome of other suits in California and Georgia has been an improvement in smelting methods, and will endeavor to force similar improvements in Montana. The Department of Justice has announced that the Montana suit will be pressed for a decree, unless Government experts can cooperate with the Anaconda company in terminating present conditions.

Institute of Metals.

The Council of the (British) Institute of Metals have decided to initiate what is hoped will be an annual series of May lectures.

The first of these will take place in London on Tuesday, May 24, when Professor Gowland, F.R.S., vice-president of the Institute, will deliver a lecture on "The Art of Working Metals in Japan," which will be illustrated by diagrams and lantern slides.

Chemists' Building in New York.

The Chemists' Building is progressing rapidly. The excavation of the site at 50-54 East Forty-first Street is nearly completed, and the bids of W. L. Crowe Company for the general construction, and of Chas. L. Eidlitz & Company for the electrical work have been accepted. A pamphlet will soon be ready for distribution among the membership of the Chemists' Club and other chemists, which will contain floor plans and other exact information. Barring unforeseen hindrances, the building should be ready for occupancy in January or February, 1911.

The chief features of the club's quarters have been previously detailed (see, especially, page 4 of our January issue), perhaps, however, some agreeable surprises will await the visitor. It has been found possible to carry out the architects' original plans in all essentials, and the building promises to be both useful and attractive.

Chemists should consider carefully the advantage of renting laboratories in the Club Building. So far, every profession has profited by concentration in a definite locality. The new Chemists' Building may seem to some rather distant from their old-time haunts; but within a year, their clients will be moving into its vicinity. The new Chelsea docks, as well as the Penn-

sylvania Station are causing merchants to consider Thirty-fourth Street the probable wholesale center; manufacturers are moving to Long Island and New Jersey; even the courts must inevitably find an up-town site.

The rentals will be moderate, and the arrangement of the flues, supply mains and chemical waste lines makes it possible to equip the laboratory according to one's fancy or needs, with the least expenditure of time and money. Then there is the proximity of a large consulting library. The possibilities of social and intellectual intercourse with men in the same line of work are multiplied to such an extent that the commercial chemist would find himself in a truly academic atmosphere.

A project will be submitted to the New York Section of the American Chemical Society at its next meeting, which, if adopted, will greatly enlarge the usefulness of the Chemical Museum for research, and here, again, proximity to a scientific center will prove advantageous to every tenant.

The Subscription Committee is not yet able to report the sale of all the stock, as $25,850 are still to be disposed of, and it is the duty of all those who desire to see the new building a success to relieve the burden of its managers as far as possible, and to do their best to interest friends in the enterprise, if they feel themselves unable to take a considerable number of shares.

The directors of the building company are Dr. Morris Loeb, Dr. C. F. Chandler, Mr. Albert Plaut, Mr. W. H. Nichols, Jr., and Dr. Leo H. Baekeland.

New York Section of the Society of Chemical Industry

At the meeting of March 25 of the New York Section of the Society of Chemical Industry (Mr. Maximilian Toch, chairman) an interesting lecture on color photography was delivered by Frederic E. Ives.

Messrs. L. H. Baekeland, Charles Baskerville, David Wesson, C. A. Doremus and Gustave W. Thompson were elected by ballot to serve on the executive committee for the ensuing year.

News from Niagara Falls

While the old established electric furnace industries of Niagara are in flourishing condition, interesting progress is also reported from the youngest of the large electrochemical works, the Hooker Electrochemical Company, which operates the Townsend process for the production of caustic soda and chlorine by electrolysis of brine. The chlorine is used in various ways, the chief product being bleaching powder; but electrolytic chlorine is now also attracting attention for metallurgical purposes.

Of special interest is the successful use in continuous commercial operation for several years of cell units with 2500 amp capacity and of very compact construction, and a recent large addition of units of 5000 amp capacity, illustrating the practical applicability of the principles of the Townsend cell. It may be mentioned that very favorable comment has been made on the cell by technical experts from Europe, who have visited the plant of the Hooker Electrochemical Company.

From the Canadian side it is reported that the works of the American Cyanamid Company in Niagara Falls, Canada, are in satisfactory commercial operation. The manufacture of commercial fertilizers from calcium cyanamide is stated to differ in various respects from European practice. The process of the American Cyanamid Company has been worked out to suit exactly the conditions of this country, especially the demand for a so-called complete fertilizer.

From Welland, Welland County, Ontario, it is reported that at the works of Electro Metals, Ltd., where ferrosilicon is principally made, extended experiments have recently been made on the baking of very large amorphous carbon electrodes. As is well known, this is a problem the solution of which increases in importance and difficulty with the increase of size of electric steel furnaces now being erected in various parts of the country.

The Iron and Steel Market.

April has brought fresh disappointment to the iron and steel trade, not because it did not bring an improvement in the market, but because it did not bring as great an improvement as was expected. While in the preceding months of the year actual engagements fell short of production, it is probable that on the whole fully as large a tonnage of finished steel was sold in April as was produced. In a sense the industry was "breaking even," but the spring is naturally the time for heavy buying, and unless general business conditions improve, buying is likely to be lighter in June, July, and August.

Upon the markets for wire and pipe there rested a heavy burden upon the opening of spring. In the closing months of last year buying in these lines, particularly by jobbers, was very heavy, and very large stocks were accumulated by reason of the general promise of the steel industry of higher prices this year. Through the winter the mills continued at full pace, and accumulated stocks of their own, so that the spring trade had two sets of stocks to liquidate. The movement into actual consumption was probably fully up to normal, taking care of the jobbers' stocks, but as there has been no particular prospects of price advances the jobbers have not bought heavily, and the mills are left with stocks. In no other branch of the finished steel trade has there been any curtailment of production, so far as can be ascertained, but in pipe and wire there has been curtailment, the Lorain pipe plant being closed during the early part of April and running at reduced output the remainder of the month, while the largest independent wire plant in the Pittsburg district closed April 9 for a short period to reduce stocks.

Other branches of the finished steel market have had sufficient vitality to maintain full production and the present outlook is for a continuance of full output for several months. At the same time the market entirely lacks the snap which has characterized the recent bursts of activity. In the three years of continued high pressure, from late in 1904 to late in 1907, mills were steadily falling behind in deliveries for more than two years, and prices were advancing, although not rapidly. Although business suddenly collapsed at the end of October, 1907, there was an advance in wire products on September 3 preceding, and a few months prior to that, on May 14, there was a large advance in pipe. At present the market shows none of that advancing tendency, although demand and production are 25 per cent. greater than in that period. The difference is made by capacity having increased just a trifle more than demand.

So far at least there is no evidence that the market is suffering from the fact that all efforts at artificial control were abandoned over a year ago. It is quite likely that if there had been artificial control during the second half of last year prices could not have been advanced as rapidly as they were by the eagerness of buyers to take what they considered bargains. They would probably have doubted the permanence of the advances, and this year, with demand less than was expected, they would probably have felt that prices were being artificially maintained, and would have bought less freely than they have in the actual circumstances, when it is known that each producing interest is working by itself.

Finished steel prices are substantially the same as at the opening of the year. From time to time there has been shading in some products, notably sheets and wire products, but the market has not become quotably lower. In structural shapes there has been a gradual weakening, by $1 a ton, and this concession, made early in the year only by Eastern mills, has in the past month become quite general.

Pig Iron.

From November 1 to April 1 pig iron production has averaged

each month at a greater rate than 31,000,000 tons a year, while October fell only a trifle below that rate. February showed the highest rate, 31,600,000 tons; March showing a drop of 400,000 tons to 31,200,000 tons. In no calendar year has as much as 26,000,000 tons been made, so that the industry has been running at a stupendous pace. The decrease in production in March was wholly by steel works, the merchant furnaces increasing their output. This was unnatural, for the merchant furnaces have been accumulating stocks, and should have reduced production. They have been doing so of late, several stacks having gone out in April, while more are certain to go out in the next two months. Prices have continued to weaken, although very slightly. Prices at valley furnaces (90 cents higher, delivered Pittsburg) stand quotable at $16 for basic, $17.50 for Bessemer, $15.75 for No. 2 foundry, $16 for malleable and $15.25 for forge. The Southern market has dropped 50 cents since last report, being quotable at a minimum of $12. At this figure there is the first definite resistance to decline. The Southern furnaces, however, have a larger margin than have the Northern furnaces, which must buy ore and coke. Some Central Western furnaces have not bought ore for the season, and perhaps will not unless conditions improve, preferring to go out of blast. For the first time the competition of furnaces owned or controlled by ore interests promises serious results to the purchasing class, for there is now a large production by them, and more are being built by ore interests, for no less than eight merchant furnaces at Chicago, Detroit, Cleveland, Josephine and Buffalo, are being built by Lake Superior ore interests, two of these, at Detroit and Cleveland, being practically completed.

Steel.

Bessemer steel has weakened, while open-hearth steel is, if anything, stronger than it was a month or two months ago. The weakness in Bessemer steel is directly attributable to the light demand for rails. A Bessemer steel interest just east of Pittsburg has lately become a producer of sheet bars and entered the Pittsburg market early in April with cut prices on both billets and sheet bars. Prices are roundly quotable as follows: Bessemer billets, $27 to $27.50; sheet bars, $27.50 to $28; open-hearth billets, $28.50 to $29; sheet bars, $29 to $29.50; all f.o.b. maker's mills, Pittsburg or Youngstown districts. Rods are nominally $33, Pittsburg.

Wages.

Early in April the Pennsylvania Steel Company, for its own operations at Steelton and the Sparrows' Point operations of its subsidiary, the Maryland Steel Company, announced a wage advance of about 6 per cent. Shortly afterwards the United States Steel Corporation announced an advance, for May 1, averaging about 6 per cent. for its blast furnace and steel works employees in the North. There had been an advance in Connellsville coke wages January 16 and an advance in the Lake Superior ore region at the beginning of mining. The question of advancing wages in the South, and of advancing wages upon its railroads, was left undecided. Other iron and steel interests in the Central West will presumably be moved by the incident to make corresponding advances. Many of the railroads have made wage advances averaging about 6 per cent.

These wage advances are based upon the unrest of labor and the "increased cost of living." As shown by the Index numbers of commodity prices, there has been a decided increase in the cost of living since 1907. The steel industry, however, is obtaining from $3 to $5 a ton less for its products than in 1907, and while prices were slightly higher, on an average, than in 1906, there was a general wage advance at the beginning of 1907. There has been no wage reduction since 1907, except that in the spring of 1909 there was an abortive movement to reduce wages, but former wage scales were soon restored.

Thus the steel industry is paying higher wages and getting less for its product. The trend is a very unfortunate one. The cost of steel production is altogether too high for the circumstances in which the industry finds itself.

Finished Products.

Regular prices, f.o.b. Pittsburg, are as follows:

Standard steel rails, $28 for Bessemer, $30, for open hearth; f.o.b. mill, except Colorado.

Plates, $1.55 for tank quality, ¼ in. and heavier.

Shapes, $1.50 to $1.55 for I-beams and channels, 15 in. and under, zees and angles, 2 x 3 and larger.

Steel bars, $1.45 to $1.50, base.

Iron bars, $1.60, Pittsburg; $1.50 to $1.60, Philadelphia; $1.50, Chicago; $1.40 to $1.45, St. Louis.

Wire nails, $1.85, base; plain wire, $1.65, base; galvanized barb wire, $2.15.

Black sheets, 28 gage, $2.40; galvanized, $3.50; blue annealed, 10 gage, $1.75 to $1.90; plainted corrugated roofing, $1.70 per square; galvanized, $3.

Tin plates, $3.60 to $3.75 for 100-lb. cokes.

The Non-Ferrous Metal Market.

Practically no interesting features have characterized the base metal market for the past month, and no transactions worthy of note have been reported. Temporary improvement has been noted on one or two occasions, but there has been a general evidence of weakness. The feeling prevails that the delay in the anticipated spring buying has contributed to the lack of firmness in the market.

Copper.—The only feature in the copper market in the last few weeks was the sharp decline in lake on April 11. This followed a period of dullness, and was due to the decision of the Calumet and Hecla to offer copper at 13c. instead of 13.75c. The effect was to stimulate sales, both foreign and domestic, and some good orders were booked. The action of the Calumet and Hecla may have been influenced by the American statistics for March, which were regarded as unfavorable on account of the increase in the world's visible supply. Electrolytic has shown the same features as lake.

Tin.—The market for tin has been unsteady and unsatisfactory, with practically no demand. Domestic sellers recently offered the metal below the import basis, but buyers did not take much for future delivery. Prices have varied a little during the month, but at the close of the market on April 13 tin could be bought at 32.40c.

Lead.—This metal has shown a steady decline for several weeks. The reluctance of the consumers to buy at the prices offered has resulted in a dull market. The reductions made by the American Smelting and Refining Company have been met promptly by other sellers, but no large sales have been made. At the close of the market April 13 lead was easy at 4.35 to 4.40c. New York, and 4.20 to 4.22½c. St. Louis.

Zinc.—Nominal prices have been the rule for some weeks, and liberal offers failed to find ready buyers. Prices have dropped steadily until the close of business April 13 showed spelter offered at 5.50c. in New York and 5.35c in St. Louis. Other metals except aluminium have shown little or no feature. Business has been active in all branches of the aluminium trade and the production is being bought up steadily.

CORRESPONDENCE

Electric Steel Refining.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The article in your April issue on the South Chicago Electric Furnace Plant of the U. S. Steel Corporation is of considerable interest. After we have heard so much as to what could or might be done with the electric furnace in the electrometallurgy of iron and steel, it is refreshing to read a simple statement of what is being done in South Chicago with the 15-ton Héroult steel-refining furnace on a thoroughly commercial scale in every-day work.

While the object of your article was evidently to state

simply facts, without any theoretical discussion, some interesting deductions can be drawn directly from the facts given in your article. The question has often been asked what is the rationale of the success of refining steel in the electric furnace and the answer has usually been that two causes are contributory to success—the possibility of producing a very high temperature and the neutral or reducing atmosphere of the electric furnace.

Now, the figures of temperature given in your article show conclusively that the possibility of producing a very high temperature in the electric furnace is not utilized for steel refining, at least not in the practice of the Illinois Steel Company at South Chicago. The steel in the electric furnace is not much hotter than when it comes from the Bessemer converter. Hence the success of refining steel in the electric furnace should be attributed essentially and primarily to the neutral atmosphere alone, which permits reactions (deoxidation and the specific reactions in the Héroult furnace by which sulphur and phosphorus are removed) which are impossible in oxidizing furnaces.

Chicago, Ill. M. N.

Rapid Electro-Analysis with Stationary Electrodes.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—I notice in your April issue an abstract of an article by Perkin and Hughes in which they describe some new forms and details of rotating electrodes for the quantitative determination of metals by electrodeposition. A number of articles have appeared lately dealing with this subject, interest being aroused to a great extent no doubt by the advantage, and in many cases by the necessity, for more rapidity.

This being the case it seems strange that an article by Dr. John T. Stoddard, which appeared in the *Journal* of the American Chemical Society for March, 1909, in which he brings out the merits of the stationary wire gauze cathode, should have received apparently so little attention. This article has been abstracted and, I believe, reprinted in full in the *Chemical News*. Also, other experimenters, for instance L. S. and R. C. Palmer, in a paper read in May, 1909, before the American Electrochemical Society, have confirmed to a large extent the results obtained by Dr. Stoddard, but in spite of this publicity many investigators, notably Perkins and Hughes, do not appear to be aware of the method as suggested in that article, or, if they are, do not consider it of importance.

In the opinion of the writer it is worth very serious consideration, especially as Dr. Stoddard has worked out the details as they occur in actual laboratory work quite thoroughly, and in adapting it to the work in this laboratory few changes were made, and these only in some comparatively unimportant details.

Some time previous to the appearance of this paper the increase of work in this laboratory necessitated some more rapid method for the determination of copper, and the rotating anode was tried with both a platinum dish and a mercury cup for the cathode. In spite of the time saved by the rapid precipitation it was soon recognized that in a laboratory connected with a manufacturing plant where "results" are wanted with as much rapidity as is consistent with accuracy, rather than "material" for papers, the apparatus necessary to the rotating method was not, to say the least, desirable.

Dr. Stoddard's article appeared about this time and was recognized as a step forward, provided it proved practical and accurate, which it has.

In this laboratory the gauze cathode is the same as described by him, and is a cylinder 1¼ in. in diameter by 1¼ in. in length, made of 52 mesh platinum wire gauze. At each end of the cylinder the gauze is folded over a platinum wire 0.02 in. or 0.03 in. in diameter, and the whole soldered to a platinum wire stem about 0.05 in. in diameter and about 6 in. long, the cylinder complete weighing about 10 grams.

The anode is a platinum wire (0.05 in. in diameter) spiral with seven or eight turns in a length of ¾ in., with enough extra wire to make a straight stem 2 in. or 3 in. long. The outside diameter of the spiral is 7/16 in.

This anode is different from that described by Dr. Stoddard. It was intended to follow his description and use a platinum foil cylinder for the anode, but through some oversight none was on hand when everything else was ready for a start, so in order to get quick action a platinum wire was coiled up in a spiral form and pressed into service. It was so successful, appearing to possess the slight advantage of allowing better circulation of the electrolyte, that it has been retained.

At first, naturally, strong currents and rapid deposition were in order. With a current of 8 amp (furnished by a storage battery), or even more sometimes, the copper in a 1 gram sample of brass containing 85 per cent copper was precipitated in 12 or 15 minutes. It was found after a time, however, that this speed carried disadvantages—disadvantages, by the way, which are not necessarily overcome by the rotating electrode. The last traces of copper were apt to be left in the solution, and it required close attention, on the other hand, to see that the strong current did not decompose all the acid, indicated by a tendency to foam, and in this way spoil the work.

The current was dropped to 6 amp and the time at this rate was about 20 minutes, with better results. Gradual changes were made, based on more experience, until now the start is made with 4 amp (increased to five or six for the last few minutes), and the time allowed is 30 minutes.

At this rate, working on a 1 gram sample, it is very rare indeed that the last traces of copper are not removed, whether it is a yellow brass containing 60 per cent of copper, or a sample of ingot copper containing practically 100 per cent, and on the other hand, there is no danger of the acid being all decomposed. It is just as simple as, and requires no more attention than, the old over-night method, and yet is comparatively rapid.

The deposition of the copper is made in a volume of 60 c.c. to 70 c.c. and at a temperature nearly or quite boiling. In the regular course of a brass analysis the electrolyte would contain 5 c.c. of concentrated sulphuric acid minus what would be lost in evaporating for the lead determination, and to this is added ½ c.c. strong nitric acid. Under these conditions the precipitation is very simple and satisfactory.

The method is equally advantageous in the determination of nickel which is deposited under practically the same conditions as copper, with the exception that the current is usually on a few minutes longer. There has been little occasion or opportunity to experiment with metals other than the above, but Dr. Stoddard's work would indicate that it can be employed to advantage on other metals.

ALLEN P. FORD.

Laboratory, Crane Valve Company, Bridgeport, Conn.

Efficiency of Dryers.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—Mr. Ruggles' reply to my criticism—not of the dryer test,—but of a misuse of the word "efficiency" in describing the performance of the machine hardly seems sufficiently to justify the new and unprecedented meaning with which this term has been invested by him.

I believe it will hardly be questioned that the definition I have given of "efficiency," as applied to the performance of any machine, conveys its meaning as universally understood by engineers and scientists, and any technical man on hearing that the efficiency of a machine was 85% would instinctively understand this as being meant in the ordinary and accepted sense.

Mr. Ruggles is perfectly correct in saying that he had fully stated his position as regards "loss of heat in dried material,"

in a preliminary paragraph, but while as he says, "there could be no possible deception," there is, in this misuse of words, abundant opportunity for grave misconception as to the performance of the machine,—the more so as the article was introduced by a comment on the remarkable efficiency attained.

True, the discussion is one of terms. What other form could such discussion assume? It may be open to the stigmatization of being "academic," but not necessarily therefore unprofitable, for, if it be legitimate to use one word in a novel and entirely arbitrary sense, widely differing from its accepted technical usage, where shall the line be drawn? Why may not the next account of a dryer test use B. T. U. with a new and special value to suit the exigencies of the case?

While the discussion may be academic, the correct understanding of the performance of a machine is intensely practical. With some uncertainty as to whether "academic" or practical, I would point out that Mr. Ruggles' defence of his method of computing "efficiency" (in his second paragraph) is not valid, nor is the distinction drawn between "necessary" and "un-necessary" losses a correct one.

The losses (departures from theoretical perfection) in any well designed machine are all necessary. Good design reduces losses to a minimum. Unnecessary losses are, de facto, the marks of poor design.

Loss by radiation in any heat-using machine is, practically speaking, a "necessary" loss. It can, in no practical way, be avoided, but, by good design, may be reduced. Similarly in any fuel-burning machine loss by unconsumed fuel is unavoidable and, therefore, necessary, but, by good design of furnace, it may be reduced to a minimum.

In a dynamo, loss by heating of the armature is "necessary," and so on indefinitely. With precise similarity, loss of heat in dried material is inseparable from the operation of any practical dryer, but may be minimized by modified design or mode of operation.

In every case cited, in speaking of the efficiency of the machine we mean its utilization of energy *in useful work after deducting all losses* and not after crediting the machine with one of the major losses on the ground that it is necessary.

Nor is Mr. Ruggles correct from a purely practical standpoint in assuming that "it is necessary to heat such material (sand) to 212°." Nor again, that "to attempt to dry sand, etc. * * * at a low temperature by absorption would be absurd on account of the small capacity such a process would give." If I correctly understand the last quoted sentence, "drying at a low temperature by absorption" means drying under such conditions that all the moisture is carried off as vapor by the air (or gases) passing through the dryer, such gases being discharged partly or completely saturated at a temperature below 212°. If this understanding be correct, such a process would by no means be absurd; nor, to attain a capacity equal to that described in the test under discussion, would it involve any extraordinary conditions—either as to size of apparatus, initial temperature, volume of air, or in any other way. Furthermore, it is entirely practicable to discharge the dried material at a temperature far below 212° and hence greatly to diminish the "loss of heat in dried material."

This loss, which in Mr. Ruggles' case far exceeds any other, is, as I have already pointed out, one of which the magnitude is largely dependent upon the design of machine—one which can be materially reduced and which differs in no essential from any other source of loss. There is absolutely no legitimate reason for according to it a special treatment.

Mr. Ruggles' position would be correct only if the dryer be considered as a machine for *heating* sand. Such is not its true function, which is purely evaporation of water, and any heat diverted from the true function of the machine is wasted as regards the specific end to be attained and, therefore, detracts from "efficiency."

The 85% efficiency claimed represents no real thing. It stands for no actual tangible accomplishment of the dryer and conveys no correct concept of the merit or demerit of its performance. The 85% efficiency is a fanciful and ideal figure, compounded of the actual useful performance in drying, and the useless waste of heat in dried material. If it means anything at all, it must be regarded as expressing the compound efficiency of the machine as a dryer and a sand heater.

"Efficiency" has hitherto been a useful and respectable member of the community of words, but we may well shudder for its future reputation, if such hybrid and illegitimate concepts are to be fathered upon it.

To sum up:—My letter in your April issue was a protest against using "efficiency" in a sense differing radically from its accepted technical meaning,—a transgression that is hardly palliated by a statement of position as regards a certain loss in another part of the article.

I contend that any one reading the article in question, with its deduction of 85% efficiency, would primarily understand that the dryer had, in the test described, utilized in useful work 85% of the heat supplied to it, instead of only 54.5% as was actually the case.

Only after a somewhat careful study of the figures does the fallacy become apparent, and then only to those having some familiarity with the science of drying.

Whatever the 85% represents, if indeed it represents anything, it certainly does not express the efficiency of the machine as a dryer.

Therefore, without implying any intent of deception, the erroneous use of the word "efficiency" certainly does convey, in the article discussed, a quite erroneous idea of the actual performance of the machine under test.

Bayonne, N. J. W. E. Wadman.

* * *

To the Editor of Metallurgical and Chemical Engineering

Sir:—From Mr. Wadman's point of view, taking one particular kind of material, his position may be correct, but in drying over 40 different kinds of material under the greatest variations of moisture and temperature, there can be but one way of figuring the efficiency of dryers so as to bring them all under a uniform rating, and this is the system which I have adopted and which I maintain is perfectly fair as long as the purchaser and user understands the basis of comparison.

A great many dryers are sold for drying and heating sand in asphalt work where it is necessary to raise the temperature of the sand to 400° to mix with the melted asphalt without chilling it. In this case Mr. Wadman would credit the heat carried out with the sand and make the efficiency of the dryer 88 per cent, while the same dryer drying the same sand for a plaster mill would only have an efficiency of 54 per cent.

In many other cases the material after drying has to be heated either to calcine it, to burn out organic matter, or for some other special reason. In drying granulated blast furnace slag, the water is imprisoned in cells so that a temperature of at least 250° has to be given to the material in order to burst the cells and release the water.

In some cases, as with cement rock, the moisture to be evaporated is not over 1 per cent, in which case Mr. Wadman would only credit the dryer with 22 per cent efficiency, while the same dryer drying a precipitate carrying 60 per cent of water he would give an efficiency of 83 per cent. This is rather an absurdity when the dryer in one case is as efficient as in the other. With my method of calculation any one type of dryer will give practically the same efficiency under any or all conditions and different types may be compared even under totally different conditions. By charging the dryer with only unnecessary losses, such as imperfect combustion, heat lost in exhaust, in radiation and in dried material above 212°, and by crediting it with the necessary heat of material up to 212°, no injustice is done and the question is much simplified.

New York City. W. B. Ruggles.

The New Blast Furnace of the Bethlehem Steel Company—1.

By W. S. Landis, M.S.

On Thursday, April 7, Furnace "D" of the Bethlehem Steel Company was lighted by the veteran ironmaster, Mr. John Fritz. The company had invited several hundred representative citizens of the Bethlehems and adjacent towns, as well as students of the Lehigh University, to the interesting occasion, they meeting at the offices of the company and being led by President Schwab to the new furnace, heartily cheered "Uncle John" and President Schwab as the torch was applied. After the lighting they again returned to the offices, where a reception was held, at which speeches were made by Mr. Fritz and the officials of the company. With all his long and active career in the iron industry Mr. Fritz acknowledged this as the first time he had ever set a furnace in operation himself.

Some 50 years ago this summer the first blast furnace of the old Bethlehem Iron Company was built. Four others followed it at various intervals, the four still being in active operation though the original one has long since been demolished. These four furnaces are 18 ft. x 70 ft. and have capacities of 200 tons of basic iron per day. In April, 1906, work was commenced on a 22 ft. x 90 ft. stack in anticipation of the demands of the new rail and structural mills begun in the fall of this same year. This furnace, designed by the Bethlehem Steel Company and built by the Riter-Conley Company, was the

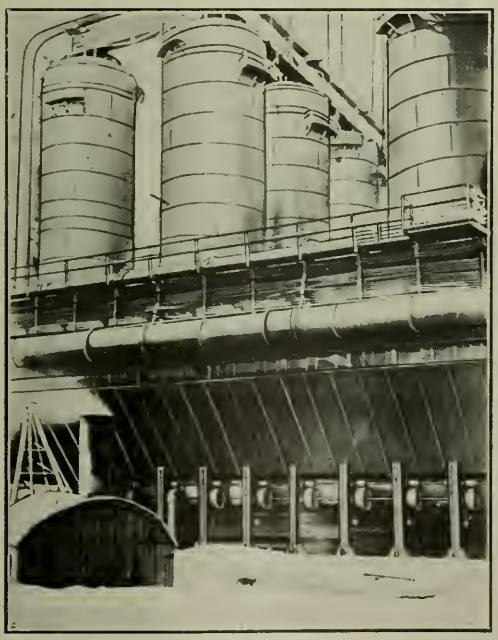

FIG. 1.—ORE BINS.

prototype of the furnace just lighted, though in lines and general arrangement only.

In 1908 the steel company determined to install an addition to their steel mills, the present 35,000 tons capacity per month not nearly sufficing to keep up with their orders. This addition is to take the form of a duplex plant, similar to the one at Ensley, Ala.

To meet the demands of this new plant for pig iron another furnace was determined upon.

Work being somewhat slack in the construction departments of the works it was determined to undertake the construction of this new furnace at home in order to keep up the personnel of the various departments during dull times. Every drawing, and every part of the furnace with the exception of a traveling crane and two motors entering into the whole construction, was built by the Bethlehem Steel Company themselves in their own shops, the construction being almost entirely in the hands of Mr. W. F. Roberts, assistant general superintendent. The entire

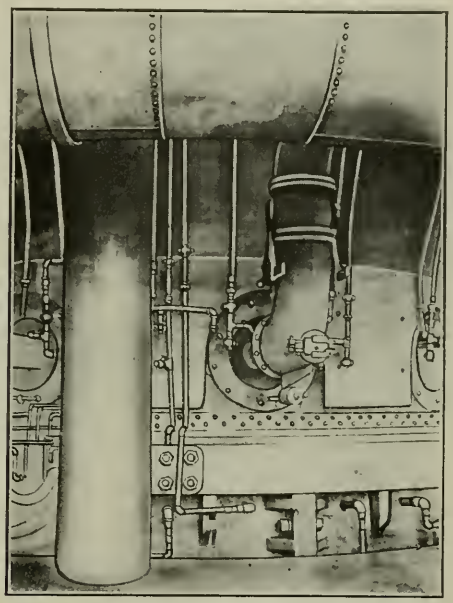

FIG. 2.—PORTION OF BOSH.

work was completed in an actual working time of eight months, and at considerable saving over contract work, both in time and money.

Although it is intended to give a complete description of the many novel features of the furnace in detail in Part II of this paper (to be published in the next issue), it might not be out of place here to call attention to the general equipment of Furnace "D." The ores used come from the Santiago district, Cuba, and are rather refractory, necessitating high temperature of blast for successful treatment. For this reason ample stove capacity in the shape of five 22-ft. x 100-ft. McClure-type stoves has been provided. To ensure these stoves working at their maximum efficiency it was necessary to provide at the same time a most elaborate system of gas-cleaning apparatus, the gases passing through a conical dust-catcher, a Mullen washer and three 12-ft. x 75-ft. Steinbart towers with interior rain-makers, before going to the stoves. Attention will again be called to this feature of the furnace.

Fig. 1 shows the ore bins with elevated railway for carrying stock from the yard to the bins. This railway is over half a mile long and extends the full length of the present furnace equipment, embracing five furnaces. Just above may be seen the stoves and to the extreme left the stack. The steam shovel in the foreground is excavating for the foundations of the new blowing house, gas engines of the company's own manufacture to be installed as rapidly as they can be built. At present the surplus power of the other furnaces is used to drive Furnace "D."

Fig. 2 shows a portion of the bosh, a tuyere connection and at

the lower left the emergency tap hole. The cooling system of the bosh is unique and will be referred to in detail later.

Fig. 3 is a general view of the interior of the cast house, the skimmer being at the extreme left. The ladle cars, carrying the metal to the mixer in a steel mill a mile away or to the casting machine, run in under the floor, the illustration showing the various runners and gates controlling the flow of metal.

The slag cars come in on a track laid in the pit between the

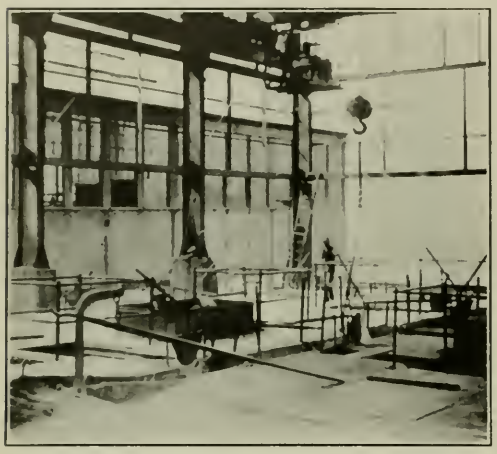

FIG. 3.—CAST HOUSE.

cast house and the boiler house on the left. A 25-ton crane has proven itself a most useful adjunct to this portion of the furnace.

One cannot help but marvel at the cleanliness of the cast house, the visit of the writer having been unannounced and no special dressing up having been done. The same cleanliness is

FIG. 4.—STEINPART TOWERS.

everywhere evident around the furnace, concrete floors with convenient sewer outlets greatly assisting in its maintenance.

Fig. 4 shows the Steinbart towers during erection. The furnace was in operation at the time this photograph was taken, the gas from the Mullen washer on the right being shunted around the towers through the large inverted siphon at the left. Similar siphons connect the washers with the gas mains, no water being used other than water admitted or run out of these siphons.

The rated capacity of the furnace smelting hard ores is 450 tons per day, using 41,000 cu. ft. of blast per minute. The total capacity of the whole blast furnace equipment at present completed is 1500 tons a day. With the completion of the duplex steel plant it is estimated that at least 2500 tons of pig per day will be required.

The company has, therefore, let contracts for two similar furnaces to "D" to the Pennsylvania Engineering Company, of New Castle, Pa., work on which has just been started. An interesting feature of this new work is the large traveler used for handling the material entering into the construction of the 10 stoves and two stacks.

Fig. 5 shows it in operation setting plates on one of the stoves of furnace "F." It is 125 ft. high, weighs 140 tons and cost alone $10,000. The boom is 90 ft. long, sufficient to reach to the furthest stove on the left. The extremely heavy bracing in the lowest story is necessitated by the fact that the traveler spans the track leading to the slag tap of furnace "E."

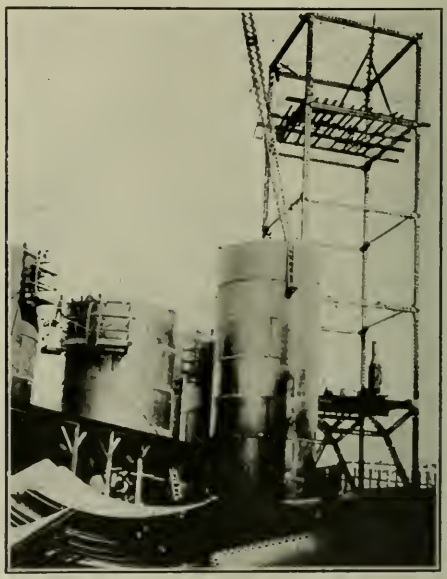

FIG. 5.—TRAVELER.

In concluding this portion of the description the charge sheet of the furnace for its first filling will be given. The furnace was scaffolded as usual, 16 ft. of cord wood being used. Next 21 rounds of coke (10,000 lb.), 21 rounds of blast-furnace slag (2000 lb.), and 21 rounds of stone, half dolomite and half calcite (1600—2100 lb.). Then 7800 burden was added per round of coke, this being increased by 400 lb. each fifth round until the full charge in the furnace, limestone increasing correspondingly 100 lb. every tenth round. At 3.30 p. m. the torch was applied. At 4 p. m. the blowing engines were started at 9000 cu. ft. of air per minute. Slag was tapped 17 hours after lighting and iron 24 hours.

Columbia Night at the New York Chemists' Club.—The smoker held at the Club House on March 26 was the second in the series of college evenings which are being given by the Club. This time it was Columbia night and a representative delegation from the faculty was present, including Dr. Chandler, Dr. Rogers, Dr. Metzger, Prof. Gies, Prof. Sherman, Prof. Coblentz and Prof. Woodhull. Prof. Morgan and Prof. Tucker had sent papers.

Electric Furnaces in Non-Ferrous Metallurgy.

BY JOSEPH W. RICHARDS.

The electric furnace is monopolizing attention to such a great extent in the metallurgy of iron and steel that its use in the metallurgy of the other metals is being relatively neglected. The interests involved in the manufacture of iron and steel are so great that any suspicion that the electric furnace is able to bring about a revolution in the manufacture of pig iron, structural steel or fine steel, focuses the attention of metallurgists on these possibilities.

Signs are not lacking, however, to indicate that non-ferrous metallurgy may likewise be deeply concerned in the development of the electric furnace. The recent great advances in electric steel furnaces have given us furnaces of great capacity, which are equally suitable for use in non-ferrous metallurgy. The electric shaft furnace for pig iron manufacture is simply an improved electric shaft furnace suitable for any kind of shaft furnace work, and may quite possibly find as large application in non-ferrous metallurgy as in the manufacture of pig iron.

The furnace operations of non-ferrous metallurgy are very diverse; the principal ones are:

(1) The melting of metals for refining and casting.

(2) The melting together of metals to form alloys.

(3) The roastng of sulphide and arsenide ores.

(4) The concentrating smelting of raw or partly roasted ores to matte.

(5) The reducing smelting of raw or roasted ores to metal.

(6) The reducing smelting of raw or roasted ores to metal vapor which is to be condensed.

I. The non-ferrous metals are in general so valuable and so easily injured in quality by furnace gases that they are usually melted in pots, crucibles or muffles. The same is true of fine steel, up until recently melted only in crucibles. The great development of electric steel melting furnaces has a direct bearing on these non-ferrous operations. What can be cleaner and neater than, for instance, the melting of gold or silver in an induction electric furnace, using no fuel, producing no ashes, employing no agent which can contaminate the metal, carrying off no metallic vapor by the stream of hot furnace gases, and with the temperature controllable to a nicety by the revolving of a resistance-box handle? And what is true of gold and silver is true, in many cases, to a greater extent, of copper, zinc, nickel, aluminium, magnesium, platinum, etc. The advantages of the electric furnace melting of these non-ferrous metals are either unrecognized or are only beginning to be appreciated.

II. The non-ferrous industries manufacturing alloys will gain particularly by the use of electric melting furnaces. As is generally recognized, it is the atmosphere of the ordinary melting furnace which plays havoc with the quality and proportions of the alloy with which it comes in contact, while the hot gases carry off considerable quantities of metallic vapor. To obviate these losses and changes in the composition, careful melting is done in closed crucibles, with all their attendant disadvantages of high fuel consumption, cost of wear and tear, and small heats.

The electric furnace provides the means for producing at one heat a ton or even several tons of alloy, all uniform in composition, and without any necessary losses by oxidation or changes in composition. In other words, just as in the steel industry, it provides *crucible quality* metal in the large heats furnished by the hearth furnaces, and at almost the price of operation of the latter.

We confidently anticipate a great extension of the use of electric furnaces in the manufacture of such alloys as are usually made to best advantage in crucibles, such as brass, bronzes, German silver, coin silver, alloyed gold, and in general all the more difficultly fusible alloys which cannot be safely melted in the ordinary iron melting pot.

III. Turning now to the metallurgical treatment of non ferrous ores and intermediate products, we consider first the roasting operation, ordinarily undertaken to remove sulphur and arsenic. These depend primarily on oxidation by the air, at a carefully regulated temperature, which will not melt the sulphides or arsenides present. These operations ordinarily require little and sometimes no fuel, because the heat of oxidation of the ore itself furnishes considerable heat.

When the ore is thus self-roasting it is self-evident that no electrical assistance is necessary or required. Where supplementary heat is needed it may in all cases be furnished with advantage electrically if it can be furnished cheaply enough. If fuel is burned to supply the supplementary heat, the fuel itself and its products of combustion interfere with the roasting operation if they are mixed with the ore and burned by the same air which does the roasting; if the fuel is burned separately and its heat of combustion transmitted to the roasting material through the walls of a retort or muffle, then such heat is applied ineffectively. That is, with but poor heating efficiency.

In the case of using electrical energy for this supplementary heating, it has the advantage of exerting no hindering action whatever upon the roasting operation, and it may be applied either by direct heating of the ore by its own resistance or by transmission from an electrically heated resistor through the walls of the retort.

In any case, the substitution will have advantages in the roasting operation, and will be advisable if the electrical energy can be obtained cheaply enough. That will be the principal question to be considered; where fuel is dear and power is cheap, the substitution may easily be of economic advantage, especially in attaining "dead" or complete roasting.

IV. The concentrating smelting of raw ore or partly roasted ore to sulphide matte is an operation carried on on an enormous scale in non-ferrous metallurgy. There is nothing analogous to it in the metallurgy of iron with which to compare it. The gangue of the ore and fluxes unite to form a fusible slag, as in the iron blast-furnace, but the metals remain combined with sulphur and concentrate as melted sulphides, instead of as melted metal.

In some cases the charge contains so much iron sulphide (pyrites) that the heat of its oxidation by the blast is sufficient to replace all other fuel, and we have an auto-smelting operation similar in thermal characteristics to the auto-roasting previously mentioned, and known usually as "pyritic smelting." Such an operation is highly desirable where possible, because it furnishes matte and slag, utilizing only the self-contained fuel of the ore: The heat of oxidation of part of its iron and sulphur. Electric heating has nothing to do with such an operation.

In the majority of cases, however, the raw ore or partially roasted ore cannot be "pyritically" smelted, and supplementary fuel is necessary. The products of combustion of this fuel, mixed with the charge, are not favorable to the concentrating operation, since they hinder its oxidation. If electrical heating is used in such a shaft furnace, it will supply the deficit of heat needed without absorbing any of the oxygen of the blast.

Some of the electric shaft furnaces already operated would be fitted for these operations if provided with tuyeres above the electrodes in order to perform whatever oxidation of the sulphides of the charge was desired. The air supply thus furnished would have to be regulated closely to accomplish the amount of oxidation required and the production of the desired quality of matte, while the electric current would be regulated to provide the heat deficient for the smelting operation.

A furnace thus operating would probably run more smoothly than a furnace running "semi-pyritically," that is, with some fuel, because the amount of oxidation could be regulated exactly by the blast used and the heat supply by the electrical energy. It would be cheaper run electrically only where fuel was high in price and power cheap.

V. The reducing smelting of suitable raw ores or "dead

roasted" ores to metal is a different class of operation. One phase of it is distinctly analogous to the shaft furnace reduction of iron ores. The charges may be oxide of a metal, such as copper, nickel, lead, tin, antimony, even zinc together with the gangue of the ore, flux and a reducing agent.

As ordinarily operated, the charge is either heated by fuel mixed directly with the charge, as in shaft furnaces, or by fuel burned apart, as in reverberatories.

In reverberatories, enough fuel is mixed with the charge to reduce the metallic oxides, and the whole is heated by gases from a fireplace. The efficiency of such a scheme of heating is low; usually less than 25 per cent. of the heating power of the fuel burned on the grate is usefully applied to heating the charge, the rest being lost by radiation and conduction and sensible heat of the furnace gases, while the large volumes of gases superficially heating the charge usually carry off considerable metallic vapors into the chimney flues.

Electrical smelting of such a charge should be highly advantageous in respect to saving of metal, if the cost of the electrical energy compared to that of the relatively large amount of coal used made the change possible.

In shaft furnaces, fuel is mixed with the charge for the double function of chemical reduction and to furnish heat by its combustion at the tuyeres. The operation is a duplicate of iron blast furnace operation, except that in the case of somewhat volatile metals, like tin and lead, great losses may occur, while with zinc all of it would be driven out in the fume, and the shaft furnace is impossible.

For such shaft furnace reduction processes, the electric shaft furnace, as already built and operated, should prove itself very well suited. Its advantages are the absence of the large volume of products of combustion of fuel, and consequent great decrease in volatilization and fume loss; the absence of the relatively high temperature of combustion in the tuyere region, and the regulation of the maximum temperature in the furnace to simply that required for the running out of the products. These changes would increase greatly the regularity of running, and decrease to practically nothing the volatilization loss. Of course, sufficient carbon for reduction of the charge must be used, but none for fuel. The amount of electric power required would be small, even for large furnaces, since the heat requirements are not large.

Quantitative calculations can be made for any given locality, comparing the cost of electric smelting of any given ore to metal in the electric shaft furnace, with its reverberatory or blast furnace smelting. The writer is confident that there are localities where the conditions already exist which would make the electric shaft furnace smelting preferable to the older methods of non-ferrous metallurgy. The whole problem is very recent, and the questions involved have scarcely received any proper amount of intelligent consideration.

VI. Reduction to metallic vapors, with subsequent condensation thereof, is the problem *par excellence* of the zinc industry. It cannot be done in shaft furnaces, because the products of combustion of the fuel mixing with the metallic vapors prohibit their condensation. The only remedy is to enclose the ore mixture in retorts and supply the necessary heat from outside. This is highly inefficient of fuel, because the sides of the retorts are poor heat conductors, and the thermal efficiency of such furnaces is therefore very low.

Electrical heating offers great promise of revolutionizing such metallurgical operations. Electrical energy can be converted into heat *inside* the retorts, thus furnishing most economically the desired heat supply without having any but the usual gases in the retort. The problem is not a simple one. The iron and steel furnaces offer very little or no assistance in working out the problem, because no analogous problem arises in that industry. Many metallurgists are at present working on this problem, and at any time we may be able to chronicle the successful solution of the problem.

When the problem is finally solved electrically, it may result in the removal of our zinc works to cheap power supplies. Italy produces large quantities of zinc ore, for instance, but smelts practically none of it, because of lack of fuel; a successful electrical zinc furnace would enable Italy to utilize her "houille blanche," or "white coal," from the snow-capped Alps, and keep her zinc industry at home, where it should be.

We are, moreover, confident that a good working electrical zinc furnace is not far away, and when it arrives electrometallurgy will make one more change in the commercial map of the world.

All in all, may we not well say that electrometallurgical apparatus and processes are the most interesting, the most attractive, and potentially the most powerful of the chemical and metallurgical agents and reagents at our command?

Lehigh University.

Commercial Oxygen.

By Ernest A. Le Sueur.

The importance, for certain large applications, of oxygen and of atmospheres rich in that element is being more and more recognized. Strictly pure oxygen will always be relatively expensive because it must be produced by chemical or electrochemical means. It may be separated from air, by various physical methods, of a strength so nearly 100 per cent as to amount to absolute purity for all applications. The yield, however, of such an oxygen (in any physical process) compared with the total mass of oxygen in the air under treatment is so small as to render its cost excessive save for purposes consuming it by the thousands as compared with by the millions of cubic feet.

Not only can oxygen be produced in rich atmospheres at a cost a small fraction of that of substantially pure oxygen, but for all large uses the former is the only condition in which actual application of the oxygen can advantageously be made. Air contains by volume approximately one part of oxygen and four of nitrogen (and argon, etc.), and, in burning, for instance, one ton of coal, we raise at least 10 tons of diluting and useless nitrogen to the full temperature of the flame.

Now, a mixture of oxygen and nitrogen containing but 33⅓ per cent oxygen presents but two parts of nitrogen to one of oxygen, and, for a given oxidation job, throws a nitrogen burden into the reaction of only one-half of what a 4-to-1 mixture does. This is, in fact, the proper way to consider the matter, and it may be pointed out that to change a 20 per cent oxygen air to a 33⅓ per cent one by the direct addition of oxygen it is necessary to add another 20 per cent of oxygen.

An atmosphere containing 33⅓ per cent of oxygen is thus much stronger than might superficially appear, and it is, furthermore, the case that there are very few metallurgical operations to which an oxygen mixture stronger than said percentage could be supplied without producing a temperature beyond the ability of tuyeres, furnace linings, etc., to withstand. An ordinary combustion experiment in 33⅓ per cent oxygen air as compared with the same in ordinary air is of extraordinary brilliancy and might well be supposed by a person unversed in such matters to be occurring in pure oxygen.

So much by way of introduction. The processes with which the writer has had somewhat wide experience are adapted to delivering oxygen of any strength from about 40 per cent to substantially 100 per cent, but, as the latter is relatively expensive and is actually needed for but very restricted consumption, it has seemed well briefly to set out the above considerations. It is obvious that if a process delivering 40 or 50 per cent oxygen is used as a feeder to an application requiring a lower concentration, the necessary strength is readily obtained by suitable injection of air.

The work to which reference is made dates back a long time, as developments in this line go, that is to say, it is 11 years since the writer first produced oxygen (substantially pure

as well as in rich atmospheres) via the liquid condition and using pressures round 2000 lb. per square inch as the instrumentality for the necessary refrigeration. It is over nine years since he prepared rich atmospheres using the pressure of an ordinary mining air compressor, or about 110 lb.

The operativeness of the method in which oxygen is obtained in the process in question depends primarily on the fact, denied by the authorities at the time, that a "fractional condensation" from air *under moderate pressures* directly precipitates a liquid rich in oxygen. The accepted belief prior to the writer's demonstration was based on the work of Prof. James Dewar, of the Royal Institution, who had some four years earlier endeavored to investigate the relative proportions in which oxygen and nitrogen liquefy when a mass of air is exposed to partial liquefaction.

Unfortunately he arranged matters so that the only possible result was a complete liquefaction of a fraction of the air (the residue remaining isolated from the liquefaction compartment and the low temperature thereof) instead of a fractional liquefaction from the whole of it. The erroneous inference was drawn that air, in its first stages of liquefaction, could only deposit a liquid of its own composition, and the conclusion was accepted throughout that section of the scientific world that interested itself in this field of investigation. One result of this was that if a liquid, and subsequently a gas, rich in oxygen was desired to be obtained from air it was considered necessary to liquefy air as a whole and then subject it to fractional distillation.

The old process by which Linde obtained liquids rich in oxygen, which consisted in liquefying a portion of a stream of air by the combined influence of low temperature and enormous pressure and then effecting fractional distillation of a gaseous mixture weak in oxygen by a relief of pressure from 2000 lb. per square inch down to atmospheric pressure, failed to show the incorrectness of Dewar's conclusion because of the further fact, discovered by the writer, that "the higher the pressure under which fractional condensation of liquid occurs from air, the weaker in oxygen is the said condensation."

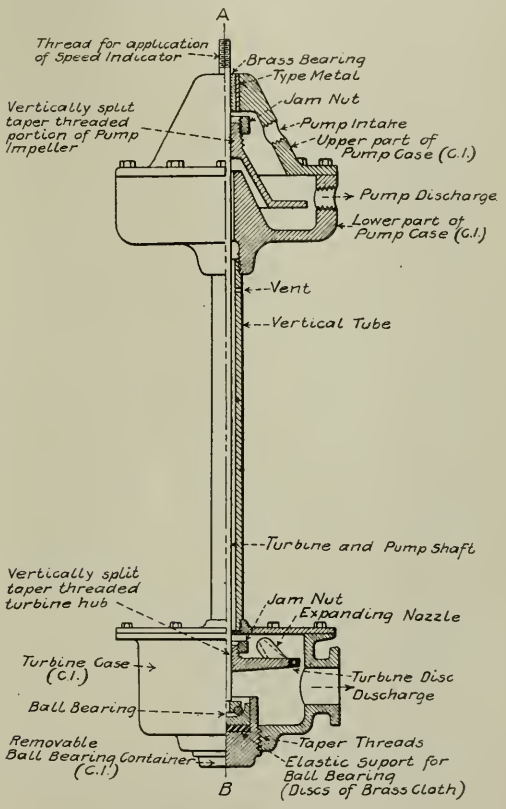
In terms of distillation the inverse holds as follows: "The higher the pressure under which a fractional distillation occurs from a liquid mixture of oxygen and nitrogen, the richer in oxygen is said distillation."

The following experiment made by me in the early days of my work in this field suffices to demonstrate the fact that the condensation, from air which has undergone a partial liquefaction, is much richer than is air. I immersed in a boiling mixture of oxygen and nitrogen much richer in oxygen than is air (and consequently boiling at a decidedly higher temperature than either the boiling or liquefying point of air proper), the lower end of an empty, unstoppered test tube of fairly large diameter (about ⅞ in.). After immersion for some minutes examination showed the tube to contain a small quantity of a decidedly blue liquid, which was found, on analysis, to contain over 40 per cent of oxygen.

The following will indicate the lines along which a cheap and efficient method of preparing fluids rich in oxygen was developed. In the first place, in order to attain anything like efficiency in the use of a gas, such as air (as distinct from a vapor liquefiable by pressure alone, like ammonia), as the working fluid of the refrigerative cycle, it is imperative that the power represented by the drop of pressure of the gas shall be abstracted as far as possible in the act of expansion. This fact has long been recognized, and Sir William Siemens attempted to liquefy air by expanding previously cooled compressed air through an engine. His apparatus was, however, totally inadequate to attain the intensely low temperature required for his purpose.

The apparatus for preparing liquids and gases rich in oxygen depends for its operativeness on the fractional condensation of a liquid rich in oxygen from air and on the development in workable form, first, of a motor adapted to abstract as much as possible of the power of the expanding gaseous residue at the point of lowest temperature, and, secondly, of a form of counter-current thermal interchange apparatus combining moderate cost with high heat interchange efficiency, and having spacious passages for the air on its way down in temperature so that trouble with clogging by aqueous frost at comparatively high temperatures and by solid carbon dioxide at very low ones is avoided.

These last requirements are almost wholly absent from apparatuses intended merely to liquefy air, because, while atmospheric air is the raw material in each case, the volumes treated by an apparatus of a given horse-power for producing atmospheres rich in oxygen are enormously greater (some 40 times) than when liquid air is the product. It was found better on the whole to allow the low temperatures developed in the process to take care of the separation of the final portions of the frost and carbon dioxide than to attempt to remove these materials completely, by any chemical treatment, from the very great volumes of air handled.



APPARATUS FOR ENRICHING AIR WITH OXYGEN.

The first motor developed in this connection (in 1900) was, in general, a de Laval type turbine disk arranged specially for the very peculiar conditions of operation. As might be imagined, the greatest problem in connection with its regular operation was to withdraw its power from it without serious losses of refrigerative effect. This might have been done (and it was originally proposed to do so) by connecting the turbine

to an electrical generator, but for various reasons a direct-connected rotary water pump was employed.

The turbine worked near the lower extremity of a vertical shaft, supported beneath on a ball bearing, in a casing from which the intensely cold exhaust (a mixture of gases rich in nitrogen and of liquid rich in oxygen) was discharged. The compressed air (pre-cooled by its course down in temperature through one set of passages in the thermal counter-current system) was admitted to the turbine guides through one of more expanding nozzles.

The shaft extended some 2 ft. vertically from the turbine case through a steel tube which enclosed it with but little clearance up to the pump casing. The pump impeller was an absolutely smooth disk (if disk it may be called in view of the shape shown in the figure) of but 4⅝ in. diameter, and the high speed of rotation gave a pressure equal to a head over 30 ft. of water.

The water was prevented from running down the vertical tube aforesaid, when the machine was idle and centrifugal force consequently not operating to drive the liquid toward the periphery of the casing, by an extension of the said tube inside the peculiarly shaped impeller. The whole arrangement is illustrated in the illustration. The water was pumped round and round, past a throttling valve, through a coil immersed in a calorimeter tank, and, as all the energy of the pump was thus transformed into heat, it was an easy matter to measure the rate at which heat was being withdrawn from the working fluid.

We thus had hot water circulating in the upper portion of the machine and cold fluids in the lower portion. With a view to preventing water vapor from finding its way down the vertical tube and freezing things up solid, an extremely small vent was provided in the upper part of said tube through which a gradual stream of cold gas from the turbine case continually passed, being driven by the slight residual pressure existing in said case and which arose from the back pressure in the pipes and passages leading the exhaust upwards in temperature. Any sudden drop in the performance of the turbine was instantly evident on the pressure of a gage attached to the pump.

In dropping the temperature of the apparatus preparatory to an oxygen run things would go smoothly down to a temperature well below that at which the apparatus could be run for liquid air in the method hereafter described, and then, all of a sudden, the turbine nozzle would start to plug with solid carbon dioxide. Save that we circumvented this by the operation described below, we could never have got the temperature any lower because we could not continue to withdraw energy (heat) from the working fluid.

The way I got over this obstacle was as follows: As soon as the nozzles plugged the supply of intensely cold compressed air was shut off and a current of relatively warm compressed air (about 75° below zero C.) was shunted in for a few seconds from a point part way down in temperature on the counter-current system. This almost instantly caused the solid carbon dioxide to vanish and we then shut down the compressor and turbine for a few minutes while we opened a valve leading from the exterior to the exhaust pipe of the turbine and poured through said valve some 30 gal. of a liquid mixture of oxygen and nitrogen.

On closing the valve and starting up again the chilling effect of this "priming charge" sufficed to carry the temperature of the turbine feed below the point at which trouble could occur in the nozzles from CO_2. The fractionating of the air into fluids respectively rich and poor in oxygen then commenced and proceeded. The liquid portion (rich in oxygen) was delivered (with or without further concentration) to the low temperature end of one of the three sets of passages of the counter-current system and the gaseous portion, or portions, delivered to a second set of passages. The remaining (intermediate) set of passages was, of course, utilized by the down-flowing current of compressed air.

The final result was a discharge from the high-temperature ends of the counter-current passages of gaseous mixtures respectively rich and poor in oxygen, the temperatures as they finally left the system being about 10° C. lower than when (as a single current of compressed air) they entered it. The oxygen runs, as we called the above, required about eight times as long to get the apparatus properly chilled off as the liquid runs, and we succeeded in making these latter many months before the apparatus had been perfected sufficiently to make the former.

For making liquid we simply ran the exhaust of the turbine through a lagged galvanized-iron drum about 16 in. diameter by 4 ft. long, containing a coil of *lead* pipe to which air, compressed by a small auxiliary compressor to about 400 lb. or 500 lb., was admitted. This air readily liquefied. In these liquid runs the efficiency of the main heat interchange was remarkably high, only about 2° difference being observed between the temperatures of the inflowing and outflowing fluids.

The reason we had the trouble with solid CO_2 at the excessively low temperature we did (just at the point at which the air was preparing to deposit a liquid condensation rich in oxygen) was because, in spite of the fact that carbon dioxide freezes at about—56°, its partial pressure, as it exists in air, is so excessively slight that it does not make its appearance until around 100° below its freezing point.

While there is very much to be said in favor of the turbine type of motor for this purpose, especially should the instrument be built by experts in de Laval construction, I nevertheless have to consider much of the above of historical interest only because I was successful later in operating a specially built "steam engine" on the mixture of liquid and gaseous constituents of air (exhausting at about 300° below zero Fahr., and incidentally leaking a little liquid oxygen at the metallic packing at the piston gland).

This apparatus, when in operation, was a sight worth seeing because the engine was surrounded by a mist and by wreaths apparently of vapor, exactly like a steam engine with a little steam blowing off, but the reason was the condensation, out of the air in contact with such parts of the engine as were unavoidably exposed without lagging, of the contained moisture as frost, with the steamy aspect familiar to all those who have worked with these intensely low temperatures.

Using the engine the trouble with CO_2 completely vanished. The power was taken off a belt-connected Westinghouse direct-current generator, and the instrument readings on same gave a continuous indication of the progress of the energy (heat) abstraction.

The results obtained fully justify the statement that, on a large scale and with cheap power, the total gross costs of the oxygen contents in a 40 per cent to 50 per cent rich atmosphere would be about 14 cents per 1000 cu. ft. While, in order to secure this figure, a production not far from 1,000,000 cu. ft. is required per 24 hours, there are many metallurgical and chemical applications requiring oxygen to which taking care of this amount would be a small matter. The plant is simple in construction and liable to but slight repair cost, which latter are included, together with interest, in the above estimate of product cost.

An experiment of some interest was tried when working on the turbine which consisted in the employment of a frozen mercury bearing for the turbine shaft. Obviously no lubrication was possible at the low-temperature end and the frozen mercury was an ideal anti-friction metal so far as the coefficient of friction was concerned. But it was too utterly soft in wearing qualities, even at very low temperatures, to give satisfaction.

I may mention that I relied almost entirely on cotton batting as a heat insulator. For special purposes, requiring a covering susceptible of being used as a plaster, a mixture of roofing tar and hair gave what were considered surprisingly good insulating properties, considering its lack of cellular character. I

may also put up a good word for lead, both in sheet and pipe, for low-temperature work. In important parts of the plant its use made practicable a form of construction which I regard as almost indispensable.

A good form of storage for liquid mixtures of oxygen and nitrogen consisted in what I called the "wasp's nest" container. It was composed of a cylindrical galvanized-iron holder, with cone-shaped top and bottom, well lagged with about 4 in. of cotton batting contained in an outer casing of tin or light galvanized iron, and then another 4 in. of batting and a final outer container. The lagging covered practically only the sides and bottom of the holder and the whole arrangement was supported by being hung by ropes from the ceiling, there being thus no props from beneath to conduct the heat into the liquid charge.

It is of interest to note that the value of the oxygen in a 50 per cent mixture as compared with pure oxygen for applications requiring a strength not greater than 50 per cent, is 0.74. That is to say, 74 parts of pure oxygen added to 126 parts of air (costing nothing) give 100 parts total oxygen in a 50 per cent mixture.

OTTAWA, ONT., CANADA.

Defects in Refractory Brick and Their Causes.

BY GILBERT RIGG.

Some time ago a friend of mine was trying to buy firebrick for a special purpose. His efforts to obtain suitable material were, to put it mildly, only moderately successful. To quote his own words, "What with the furnaceman's prejudices, the firebrick salesman's optimism, my own ideas, and the actual results, I am having a delightful time."

I am inclined to believe, judging from my own, that my friend's experience is by no means unique. The four indeterminates quoted above need to have fixed and definite values substituted for them. By bringing the first term to zero, substituting for the second set of specifications directly correlated to the third, and for the third a knowledge of the chemical and physical conditions under which bricks required for a given purpose must work, we obtain three new values by which the fourth, or the actual results, may be determined in a manner to give satisfaction to the consumer.

M. Baraduc-Muller, assistant to M. LeChatelier, in an excellent paper read before the Congress of Applied Chemistry, in London, brings a strong indictment against refractory products in general. After making a careful analysis of the factors which go to make first-class goods, which factors he afterwards combines into what he calls a "ceramo-metric coefficient" of value, he sums up the defects of what one frequently finds on the markets as follows:

"The principal defects, which the best of them show when in use, are:

"(1) Insufficient purification of material.

"(2) Methods of manufacture inadequate in mechanical power, superannuated in fact, and inappropriate for the new conditions which have to be met.

"(3) Burning at a temperature much lower than that at which the products will be employed.

"From these errors there results:

"(1) Too low a fusion point.

"(2) A lack of constancy in the dimensions of the pieces during service.

"(3) Want of compactness.

"(4) A porosity too great to resist the destructive action of gases and liquids.

"(5) A mechanical resistance too low to resist the wear of friction and shock.

"(6) Lastly: Much too great a sensitiveness to temperature changes for the prevention of cracks and fissures, which facilitate chemical and mechanical destruction."

This is a somewhat severe indictment, and in many cases, I believe, a well-deserved one. But, to be fair, some trouble arises also from lack of knowledge, on the part of the consumer, of the conditions under which the bricks are to serve. Given that these conditions are known and standarized, then the blame is entirely the manufacturer's, if he fails to meet them.

The term "refractory" is a relative one and covers a wide range of properties. Because a given firebrick does not melt down at the temperature at which it is employed, it is not necessarily refractory. Not infrequently, of two bricks with different fusion points, the one with the lower fusion point may be the more refractory under the conditions of employment.

In a case that has come under my notice, two types of firebrick (A and B) have been employed for the same purpose. A is less resistant to temperature than B, but resistant enough to withstand any temperature that can arise under working conditions. Still, if a cone test were all that was concerned, B would be classed as the better brick.

And yet A lasts five times as long as B.

The reason is not far to seek. On breaking a specimen of A we have a dense stony mass, the fracture passing through the grains of grog, which are welded into a solid mass with a bond. A broken surface of B shows the body of the brick to be a more or less crumbling mass, the grains of grog sticking out like loose teeth, and ready to fall out at a touch. Although the outside looks good, the inside is penetrated by a network of interlacing cracks.

Under working conditions A slowly wears away from the surface inwards. B falls to pieces. And B is typical of a large percentage of the so-called refractory bricks on the market. Lack of care in sizing the grog (the bricks in question contained "chunks" ½ in. in diameter), and insufficient temperature in burning, are the cause of the trouble in this case. The clay is right. The bricks are hopelessly wrong.

The properties possessed by a product which may properly be spoken of as refractory may include any or all of the following according to the conditions of service:

(1) Absolute infusibility at the highest working temperature.

(2) Complete absence of deformation and shrinkage under working conditions.

(3) Mechanical strength.

(4) Complete resistance to penetration of vapors, slags, etc.

(5) A chemical composition fitted to withstand as perfectly as possible the corrosive action of the substances to which the bricks are exposed.

(6) Equality and fixity of form and dimensions.

Let us consider these points in some detail.

A truly refractory product should be infusible at the temperature of service, not only as a whole, but as regards every part of it. A brick cannot be considered as really infusible which retains its general rectangular outline, and yet shows deep pits and slaggy patches due to particles of pyrite and other fluxes. A truly refractory product must be uniform in composition, and that composition must correspond to a melting point substantially higher than the temperature of service. Both the bond clay and the grog must conform to this condition. Very frequently they do not.

Deformation and shrinkage may be due to a wide range of factors which may be classified under two heads, composition, and temperature and duration of burning, the first set controlling the second.

The temperature at which the burning of the goods is carried out must be such as to ensure that the shrinkage has reached a maximum for the temperature of employment; the same thing applies to the duration of the burning. The readjustment in the relative position of the molecules, or particles of clay, which takes place at high temperature, requires time for its completion, different clays requiring different times. With a mixture of two clays, one high in silica, the other high in alumina, the mass burned at 1000° C. for 24 hours, had a breaking strain of

240 lb. per square inch. After seven days at the same temperature, the breaking strain was 534 lb. per square inch. The breaking strain is substantially a measure of the density and compactness of the mass.

Further, the material must be such that deformation (by softening or irregular shrinkage) does not occur. When a body of new masonry is heated, it expands. If the original burning of the bricks has not been carried out long enough, or at a temperature sufficiently high, shrinkage will supervene after the work has reached the maximum temperature, with formation of cracks and other troubles. The consumer should, therefore, know what is the maximum temperature the bricks must stand, and the manufacturers should be in a position to know at what temperature to burn his goods to ensure them against shrinkage, and what materials to use to ensure them against deformation at the temperature in question.

Under the head of deformation I include not only change of form as a whole, but also change of internal form or separation of constituent grains, giving rise to disintegration and crumbling.

A brick of high infusibility, burned at a temperature too low to ensure dense burning, and employed at a temperature too low to develop density, may not shrink seriously as a whole, but, being mechanically weak, will frequently crumble and disintegrate. Such a brick will be inferior under working temperature conditions to one more fusible and burnt dense, if the fusibility is not so great as to cause softening when in service.

The question of density is of tremendous importance in relation to the question of penetrating vapors and slags.

Whenever firebricks are to be exposed to these exceedingly destructive influences they should be burned at a temperature at which porosity is as nearly as possible zero.

The extent to which some slags will penetrate into the pores of a brick is remarkable and the effect is often disastrous. Under the microscope the pores of such bricks are seen to be filled with slag, even when the appearance to the naked eye will show nothing unusual. Comparison of a "penetrated" brick with a fresh one, at high temperatures, may indicate several hundred degrees difference in the fusion point. To quote a case from my own experience, the melting point of a fireclay mass exposed to a penetrating slag fell from over 1700° C. to 1400° C., although, except for a coat of glaze, it appeared unchanged. Under the microscope the filling of the pores by slag was plainly visible.

It is entirely illogical to go to the expense of the highest class of refractory clay to manufacture a porous product whose fusibility is bound to increase enormously under working conditions.

In dealing with this question the maximum temperature of service should be known, and the manufacturer must arrange his mixture to withstand this and burn the brick at a temperature that will reduce its porosity as nearly as possible to zero. Under these conditions the attack of the slag will be from the surface only, and the life of the brick will be greatly prolonged.

This brings us to the fifth item, or the relation of the chemical composition of the brick to the slag, etc., it must withstand. The necessity for this is obvious and is more or less recognized in connection with furnace linings.

Fixity of form and size is essential in reducing the thickness of the joints to a minimum and facilitating the work of the masons. The joints are always the weakest part of the work, as in the nature of things the mortar must be porous and more or less open in texture. Bad mason work is not always due to the mason. Some of it is due to warped and irregular brick. Moreover, the relining and repairing of a furnace is frequently carried out under hot and trying conditions when the men are not in shape to devote close care and attention to making up for the faults of the brick manufacturer.

One sometimes hears it said that "A's" firm used to turn out a first class brick for our purpose, but the quality has gone off altogether latterly." Is it quite certain that the quality of the brick has gone off in all cases? Have not changed conditions of service something to do with it? Increase of output on a given metallurgical unit unusally means increase in the severity of the working conditions. Similarly the manufacturer who loses a customer and who feels, nevertheless, that the quality of his product is as good as ever it was, has perhaps failed to recognize that the quality of his product has not kept pace with the demands of service.

Papers like the one quoted above tend to show that all is not well with much of the refractory ware now on the market. It would be interesting to know from those responsible for successful smelting operations how many would be found to curse and how many to bless? My own experience is that there is often cause for the former.

New Jersey Zinc Company.

Furnace Electrode Losses.

At the Charlotte meeting of the American Institute of Electrical Engineers, held from March 30 to April 1, two papers on furnace electrode losses were presented, the authors being Mr. Carl Hering and Dr. A. E. Kennelly. Both papers are printed in full in the March issue of the *Proceedings* of the Institute.

The paper of Mr. Carl Hering is entitled "The Proportioning of Electrodes for Furnaces." Mr. Hering explains that his investigation applies to "the electrode proper, or what might be termed the essential electrode, or the chief part of an electrode, namely the part which passes through the walls, and in which the co-operation of the two heat flows is the governing feature. Any additional parts within the furnace or projecting beyond the outside of the walls are not theoretically essential parts, even though they may be very necessary in practice: such parts are evidently determined by entirely different conditions and considerations and must be treated apart from that portion which is absolutely necessary to lead the current from the outside to the inside of the furnace. To attempt to combine the various parts of such a longer electrode and to treat them as one in an analysis for finding out the laws governing the proportions would either be impossible or would, at least, lead to endless complications rather than to a simplification." Hence, throughout the paper the proportions of the electrode, and particularly the length, refer to this essential part passing through the wall. The heat insulation of the essential part of the electrode from the surrounding walls is assumed to be perfect.

Mr. Hering sums up the results of his analysis and introduces two quantities as "true and correct measures of excellence" of materials for use as electrodes. These are the "electrode voltage" and the "specific section." They are constants for the particular materials, in so far as they are independent of the dimensions. The former concerns the power loss and the latter the size. The lower their values are the better is the material for electrodes.

Electrode Voltage.—For every material there is a fixed and definite voltage for 1° which voltage is the same no matter what the size of the electrode or the normal current, provided only that the electrode is correctly proportioned so that no heat flows through the hot end in either direction, the hot electrode end acting as a perfect heat value. This electrode voltage e in volts is

$$e = \sqrt{2\,k\,r}$$

if k is the thermal conductivity in watt, inch cube units, and r the electric resistivity in ohm, inch cube units, and k as well as r are assumed to have the same values over the whole length of the electrode. The total voltage E between the hot and cold electrode ends is then

$$E = \sqrt{2\,k\,r}\,T = e\sqrt{T}$$

where T is the temperature drop in centigrade degrees between the hot and cold ends. E multiplied by the current in amperes gives the minimum loss in watts which can possibly be obtained

with that material, for that current and temperature. On this account Mr. Hering calls E the "watts per ampere."

Specific Section.—Under the same assumption that r and k have the same values over the whole length, the relation

$$S = IL\sqrt{r \div 2kT}$$

exists between the electrode cross-section S in square inches, the electrode length L in inches ("essential length"), the current I in amperes and the temperature drop T in degrees C.

If I, L and T are made unity, that is, for 1 amp, 1 in. length and 1° C. of temperature, the resulting cross-section, now represented by s, becomes

$$s = \sqrt{r \div 2k}$$

This is called the "specific section." This is for 1° C., while for the temperature drop T, there is

$$S^1 = s \div \sqrt{T} = \sqrt{r \div 2kT},$$

which, since $S^1 = S \div IL$, is called the "section per ampere per inch length." By multiplying S^1 with the current and the length, the actual cross-section is obtained, for which the electrode is correctly proportioned so that the hot electrode end acts as a perfect heat valve.

Experimental Results.—The experimental determinations were made by the method described in Mr. Hering's Am. Electrochem. Soc'y paper (our Vol. VII, page 514). The main results are given in the following table and diagrams. The full lines in the curve sheets represent the ranges over which the results were actually measured; the dotted lines are exterpolated and "therefore, are only probable values." "There may, of course, be radical changes in these physical constants at the melting points of the metals, and at some points at which carbon may change its condition. These cannot be predicted. The present extensions are all based on a regular continuation of the measured relations."

The curves for the electrode voltage and the specific section are given in Figs. 1 and 2. In Fig. 1 they have been drawn to different scales so that they are nearly superimposed, thus enabling their relative inclinations or percentage values to be compared better with each other, while in Fig. 2 they have all been drawn to the same scale, so that they may be compared quantatively.

In Fig. 1 the curves E, which measure the minimum loss, or the watts per ampere, all have a family resemblance, except in the case of graphite. The marked difference of the graphite curve means that the losses in graphite electrodes do not grow as rapidly with the temperatures as they do for all the other materials. This, of course, is a very good quality, especially for high-temperature furnaces. For all the others the relative increase of this loss is about the same.

A comparison of the same curves E, in Fig. 2 (the heavy line curves) shows the quantitative relations of the actual losses per ampere. The much greater loss for carbon is quite striking; but, of course, there are many cases in which metals are excluded by the very nature of the furnace.

The loss for carbon is seen to be 1.55 times that for graphite.

Temperature Cent. degrees	Temperature Fahr. degrees	E Watts per ampere				S^1 Square inches per-ampere per inch length				S^1 Square centimeters per ampere per cm. length			
		Carbon	Graphite	Iron	Copper	Carbon	Graphite	Iron	Copper	Carbon	Graphite	Iron	Copper
400	752	1.00	0.85	0.145	0.095	0.00165	0.00040	0.000103	0.000016	0.0042	0.00100	0.00026	0.000041

1000	1832	1.93	1.32	0.350	0.226	0.00076	0.00024	0.000098	0.000014	0.0020	0.00061	0.00025	0.000036
1200	2192	2.15	1.43	0.410	0.270	0.00069	0.00022	0.000094	0.000014	0.0018	0.00056	0.00024	0.000035
1400	2552	2.36	1.52	0.460	0.310	0.00062	0.00020	0.000092	0.000014	0.0016	0.00051	0.00023	0.000035
1600	2912	2.53	1.62	0.510	0.351	0.00057	0.00019	0.000089	0.000014	0.0014	0.00048	0.00023	0.000035
1800	3272	2.68	1.71	0.565	0.391	0.00053	0.00018	0.000087	0.000014	0.0013	0.00046	0.00022	0.000035
2000	3632	2.83	1.79	0.610	0.430	0.00049	0.00017	0.000085	0.000014	0.0012	0.00044	0.00021	0.000035

If the current and temperature drop are given, and if the essential length is taken as the thickness of the furnace walls, the section in square inches is then determined at once by multiplying the proper temperature value of S^1 from the above table by the current in amperes and by the length in inches. If this is too large or too small to be practicable, the length may be changed and the section may be redetermined. The quotient of the section divided by the length is a constant for any specified conditions (numerically equal to S^1 from the table multiplied by the current), hence they may both be increased or decreased in the same proportion.

The loss in the electrode in watts is entirely independent of the section or length adopted, provided only that their quotient is approximately as above. It is calculated in watts by multiplying the corresponding temperature value of E in the above table by the current.

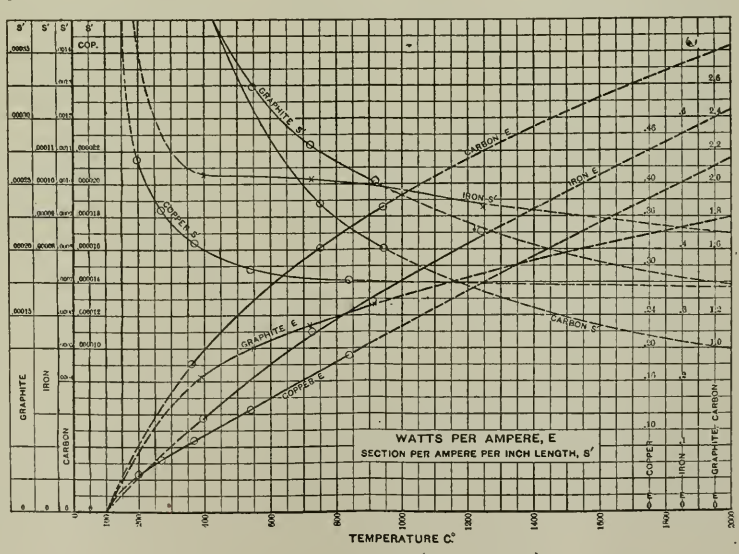

FIG. 1.—LOSSES AND SIZES. (SUPERIMPOSED.)

* * *

The paper by Dr. A. E. Kennelly deals with the "modifications in Hering's laws of furnace electrodes introduced by including variations in electric and thermal resistivity."

The assumption made by Dr. Kennelly concerning these variations is that both resistivities are linear functions of the distance from the hot electrode end. Under this assumption the integration of the fundamental differential equation leads to comparatively simple formulas, which lend themselves readily to numerical applications.

Two numerical examples are given.

The general results arrived at are summed up by Dr. Kennelly as follows:

1. The combined loss through the cold end of an electrode is equivalent to the sum of the loss by heat conduction alone (when there is no current) and approximately half the I^2R loss, the exact fraction depending on the temperature coefficients of the resistivities. With constant resistivities, the fraction will be one-half.

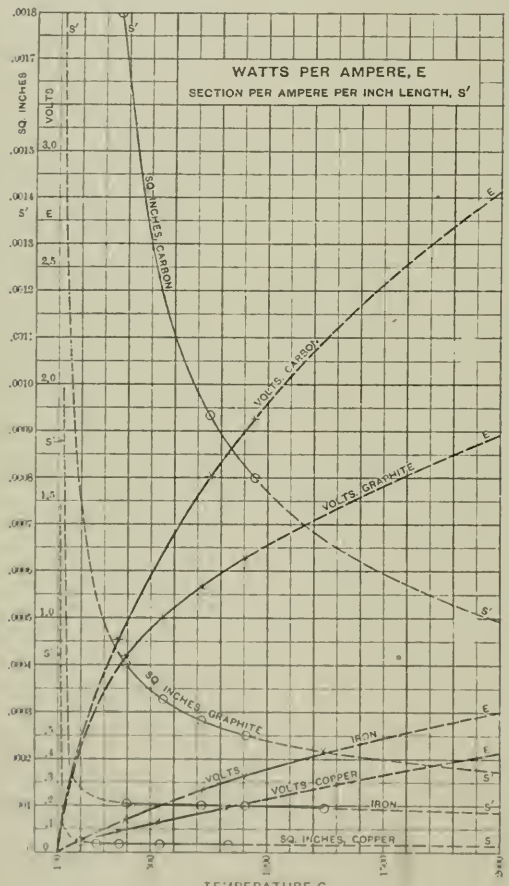

FIG. 2—LOSSES AND SIZES (SAME SCALE).

2. The above combined loss will be least when the loss by heat conduction alone is equal to the Joulean loss through the cold end.

The total loss will then be approximately equal to the total Joulean loss, and very little heat will flow into or out of the furnace.

With constant resistivities, this resultant furnace flow will be nil.

Chemical Reactions at Electrodes.*

By Reston Stevenson, Ph.D.

The following article is merely a review of the broad field of electrochemical reactions in liquid solutions and more particularly in aqueous solutions. It is in no way a presentation of new experimental research or of new theories. The writer wishes to acknowledge his indebtedness to Dr. Bancroft, of Cornell, and to Dr. Turrentine, of Wesleyan University, for suggestions and references, and to Dr. Baskerville, of the College of the City of New York, for assistance in the preparation of this paper.

In electrochemical reactions, the ions are carried to the respective electrodes, where they lose their charge and react with whatever is at hand. Obviously the nature of the ions originally in the electrolyte is of prime importance. This consideration is complicated by the fact that ionization is not always of the simple sort, such as $NaCl = Na + Cl$, but sometimes double ionic natures are displayed.

For example, Br in liquid sulphur dioxide gives upon electrolysis Br at both the anode and the cathode. Similarly, I in sulphuryl chloride gives I at both electrodes. In the electrolysis of an alkali solution with tellurium electrodes, Te'' is formed at the anode and $Te^{\cdot\cdot}$ at the cathode. $Pb(OH)_2$ may ionize in any of these ways:

$$= PbOH^{\cdot} + OH'$$
$$= Pb^{\cdot\cdot} + 2\,OH'$$
$$= H^{\cdot} + PbOOH'$$
$$= 2\,H^{\cdot} + PbO_2''$$

In an acid solution the ionic product of H_2O is exceeded and, therefore, the OH ions practically disappear, so that we have only Pb and OH ions.

In an alkaline solution, the ionic product of H_2O is again exceeded and causes the practical disappearance of the H ions so that we have only PbO_2 and OH ions in the solution.

Glycocoll dissociates thus:

$$HOH_2NCH_2COOH = H_3NCH_2C{\cdot}O'O + H^{\cdot} + OH'.$$

Of course the two dissimilar charges upon the residue neutralize each other, leaving H and OH ions in the solution.

When the electrolyte is not a single substance in solution, then the relative amounts of the different ions which are carried to the electrodes to react, depend upon the migration velocities of these different ions. Electrolytes are ionized quite differently according to the solvents[1] which are used, sometimes showing association instead of dissociation, etc.

Not only may there be a variety of ions in an electrolyte, but these ions may react in various ways at the electrodes and many of these reactions may occur simultaneously. For example, in the electrolysis of NaCl solutions, we may obtain NaOH, Cl, NaCl, NaClO, $NaClO_3$, $NaClO_4$ and O_2.

As a review of the field of electrochemical reactions, we will classify all of the various reactions which have occurred at electrodes, and then consider the variable factors concerned in the equilibrium of these reactions. The following reactions occur at electrodes:

1. The discharged ion reacts with itself
2. The discharged ion dissolves in the electrode.
3. The discharged ion reacts with the electrode
4. The discharged ion dissolves in the solution.
5. The discharged ion reacts with the solvent.
6. The discharged ion reacts with the solute
7. The discharged ion reacts with suspended particles.
8. The discharged ion reacts with dissimilar ions of similar charge.
9. The discharged ions of dissimilar charge react with each other.
10. The reaction products which are at first formed, break down and form secondary products.

* An address delivered before the New York Section of the American Electrochemical Society on March 16, 1910.

[1] Le Blanc, Whitney and Brown, Electrochemistry, p. 142.

11. The products at the electrodes diffuse and react away from the electrodes.

12. Electrolysis with alternating current.

13. Electric endosmose.

14. Electrostenolysis.

15. Reversed electrolysis.

1. The Discharged Ion Reacts with Itself.

Examples at the cathode are:

$$H^{\cdot} + H^{\cdot} = H_2$$
$$Cu^{\cdot\cdot} + nCu^{\cdot\cdot} = Cu_{n+1}$$

At the anode:

$$O'' + O'' = O_2$$

2. The Discharged Ion Dissolves in the Electrode.

For instance Na forms sodium amalgam with a cathode of Hg; H dissolves in a cathode of Pd; O dissolves in an anode of platinized platinum.

3. The Discharged Ion Reacts with the Electrode.

Cathode: Na forms an alloy with a cathode of Pb. Zn plated on Pt may alloy to a slight extent.

$$2H^{\cdot} + PbO_2' + H_2SO_4 = PbSO_4 + 2H_2O$$

Anode:

$$O'' + PbSO_4 + H_2O = PbO_2 + H_2SO_4$$
$$3Cl' + Fe = FeCl_3$$
$$4O'' + CuS = CuSO_4$$

In the electro-analysis of halides, phosphates, etc., a silver anode is used and the corresponding compounds are formed and adhere to the anode and can be weighed.[2]

4. The Discharged Ion Dissolves in the Solution.

At the cathode the solution is saturated with hydrogen and, at the anode, with chlorine, bromine, etc. The substances may be dissolved either in the solute or in the solvent.

5. The Discharged Ion Reacts with the Solvent.

Cathode:

$$Na^{\cdot} + H_2O = NaOH + H$$
$$Ca^{\cdot\cdot} + 2H_2O = Ca(OH)_2 + H_2$$

Anode:

$$SO_4'' + H_2O = H_2SO_4 + O$$
$$2CH_3COO'' + H_2O = 2CH_3COOH + O$$

6. The Discharged Ion Reacts with the Solute.

Cathode:

$$H^{\cdot} + FeCl_3 = FeCl_2 + HCl$$
$$Al^{\cdot\cdot\cdot} + 3HCl = AlCl_3 + 3H$$

Anode:

$$Cl_2(SO_4)_3 + 3H_2O + 3O'' = 3H_2SO_4 + 2H_3ClO_4$$
$$C_2H_5OH + 10I' + H_2O = CHI_3 + CO_2 + 7HI$$

7. The Discharged Ion Reacts with Suspended Particles.

Cathode:

$$C_6H_5NO_2 + 6H^{\cdot} = C_6H_5NH_2 + 2H_2O$$

Anode:

$$C_6H_6 + 2O'' = C_6H_4(OH)_2$$

8. The Discharged Ion Reacts with Dissimilar Ions of Similar Charge.

At the cathode Hg and Ag can be deposited as an amalgam from acid solutions. Zn and Cu are deposited as brass from aqueous KCN solutions. In platinizing electrodes, an alloy of Pb and Pt is deposited and the Pb is dissolved away, leaving the Pt in finely divided form. In the plating of Ni, an alloying with NH_4 is often the cause of the peeling of the plate.

At the anode, Cl and O combine to form ClO′ or ClO′$_3$.

9. The Discharged Ions of Dissimilar Charge React with Each Other.

This necessitates that the anode and cathode be very near each other. This would be of practical disadvantage in any electrochemical process.

10. The Reaction Products Which Are at First Formed Break Down and Form Secondary Products.

In the electrolysis of NaCl aq. with a Pb cathode, the alloy is formed and then the Na reacts with the H_2O and leaves the Pb as a fine suspension in the solution.

[2] Smith: Electro-analysis, p. 296.

With a Cd anode in a $Na_2S_2O_3$ solution, there is formed CdS_2O_3, which reacts thus:

$$CdS_2O_3 + H_2O = CdS + H_2SO_4$$

11. The Products at the Electrodes Diffuse and React Away from the Electrodes.

In the preparation of NaClO, the NaOH at the cathode meets the Cl from the anode and forms the hypochlorite. In the electrolytic preparation of $PbCrO_4$, the electrolyte consists of $NaNO_3$ and K_2CrO_4. The NO_3 attacks the Pb electrode and the $Pb(NO_3)_2$ reacts with the K_2CrO_4 to form $PbCrO_4$ away from the electrodes. In the production of Scheele's green, the electrolysis of Na_2SO_4 yields Na and SO_4 ions. With the Cu anode, $CuSo_4$ is formed. At the cathode, NaOH is formed, which reacts with the As_2O_3 around the cathode, to form Na_3AsO_3. The anode and cathode products diffuse and react to form Cu_2HAsO_3.

12. Electrolysis with Alternating Current.

In the application of the alternating current to a reversible cell such as Cu — $CuSO_4$ — Cu, then the same amount of Cu is dissolved at either electrode with the current in one direction as is deposited by the reversed pulsation. The Cu goes into solution and precipitates with practically equal ease. If, however, the Cu electrodes are in a KCN solution then the Cu which dissolves forms a compound with KCN which has only very few Cu ions. From this solution, the Cu is precipitated with much greater difficulty than it dissolves, so that with the alternating current, the Cu dissolves by a zig-zag movement in which the zig is always longer than the zag. In a 4 normal solution of KCN, 75 per cent Cu is dissolved when there are 10,000 alternations per minute, 55 per cent with 20,000 alternations, and 40 per cent with 300,000 alternations. Zn and Ni also dissolve in KCN solutions with alternating current. Ag is practically insoluble in KCN solutions when the alternations exceed 4000 per minute.

13. Electrical Endosmose.

Consider a liquid in contact with a solid, such as the glass walls of a capillary tube, or solid colloidal particles of Au, Pt, $Cr(OH)_3$ dyes, such as indigo, methyl violet, etc. Upon these bodies, in contact and moving past one another, are dissimilar charges of electricity. Upon that body which has the greater dielectric constant (usually water), there is a positive charge, and there is a negative charge upon the other body. Therefore, upon passing a current there is a separation at the different poles. When the solid is fixed stationary, e. g., glass tube, wood, etc., then the water alone moves to the cathode.

14. Electro-stenolysis.

Consider a salt solution in a beaker and in a test tube which stands in the beaker. The test tube is cracked, so that the two solutions are separated by capillaries. An electrode is in each vessel. Upon passing a current, water goes (c.f. 13) to the cathode and the capillaries are left negatively charged. Therefore positive ions of metal are deposited in these capillaries, but the amount of metal is microscopic because of the large charge on an ion and the small charge on the glass. However, the amount of metal becomes noticeable when it takes part in the conduction of the current and does not dissolve at its anodic end. Such a condition is obtained with the platinum metals and with metals which form insoluble oxides at the anode, such as Co.

15. Reversed Electrolysis.[4]

At the cathode occurs reduction and at the anode oxidation, but the apparent action at these respective electrodes may be reversed. This occurs when the reduction product at the cathode is an active oxidizing agent. When a dilute solution of HNO_3 containing KI is electrolyzed with Pt electrodes, the HNO_3 is reduced to HNO_2 at the cathode. The HNO_2 oxidizes the KI setting iodine free at the cathode. In the electrolysis of a solution of $KMnO_4 + H_2SO_4$, with Pt electrodes, the

[3] Le Blanc, Whitney and Brown, Electrochemistry, p. 157.
[4] Turrentine, Trans. Am. El. Soc., 1908, Vol. 13, p. 281.

$KMnO_4$ is reduced to MnO_2 at the cathode with a simultaneous evolution of oxygen at the cathode. Probably the $KMnO_4$ is reduced to Mn_2O_3, which spontaneously reduces to MnO_2 with the evolution of oxygen.

Upon electrolysis of Fehling's solution between Pt electrodes the tartaric acid at the anode is oxidized to formic acid which reduces the cupric salt with the deposition of cuprous oxide on the anode. Upon the electrolysis of a solution of $AuCl_3$ in methyl alcohol with Pt electrodes, at the anode the alcohol is oxidized to formaldehyde which reduces the $AuCl_3$ and causes the deposition of Au upon the anode. Upon electrolysis of a solution of Na_2SO_4 with a Mg anode, the Mg is oxidized to $MgSO_4$ which reacts with the water to set free hydrogen at the anode.

Of these reactions, the nature, direction, extent and velocity may be affected by the following variable factors of equilibrium: temperature, pressure, concentration and nature of electrolyte, current density, light, diffusion, e.m.f., nature and concentration of electrodes, and catalytic action. In any one reaction many or all of these factors might change so that the effect would be the resultant of many different forces. In the following pages will be considered the effect of the variation of some one of these factors while the others remain constant. These three generalizations apply at the condition of equilibrium: the phase rule, the law of mass action, and the theorem of Le Chatelier.

1. **Temperature.**

In all electrochemical preparations, e. g., iodoform, aniline, etc., there is always a narrow range of temperatures within which the greatest efficiency is obtained. Above 300° Na is deposited from the fused salts, but if the temperature is too high, the Na reacts with the bath and the yield is greatly lowered. Similarly, for Ca, Ba, and Al. In the electrolytic formation of persulphates, percarbonates, perchlorates, etc., the temperature must be kept low because these compounds decompose upon heating. In the electrolysis of an aqueous solution of HCl, when the anode is kept cold, chlorine hydrate is formed in crystals. In the electrolytic preparation of NaClO, increased temperature causes the formation of chlorate.

In general, the increase of temperature causes the increase of the diffusion of the electrode products, the velocity of migration of ions, the dissociation of the electrolyte, and the speed of reaction. That reaction which occurs with an absorption of heat would be promoted by an increase of temperature.

2. **Pressure.**

The effect of pressure is rarely studied in electrochemical reactions. Usually, a large change of pressure accomplishes only a slight variation in the point of equilibrium. In general, it may be said that an increase of pressure would promote that reaction which occurs with a diminution of volume (theorem of Le Chatelier).

3. **Concentration and Nature of Electrolyte.**

Since the reactions at electrodes are usually reactions with the electrolyte, the nature and concentration of the electrolyte is all-important. In reversed electrolysis, it has been seen that the nature of the electrolyte can reverse the apparent action of the electrodes. In the preparation of NaClO, if the solution becomes acid, the free HClO oxidizes the hypochlorite to chlorate. If the NaClO becomes concentrated, it diffuses to the cathode and is reduced. In the electrolysis of $CuSO_4Aq$, in neutral solutions at 100°, Cu_2SO_4 is formed which hydrolyzes and Cu_2O is formed. In concentrated HNO_3 solutions and in very concentrated H_2SO_4 solutions, no Cu is precipated because of the greater rapidity of solution than of precipitation. Similarly, Li is not deposited from water solutions, but is from a pyridine solution which conducts the current and does not dissolve the Li. In the electrolysis of HNO_3, with a Pt anode and a Hg cathode, hydroxylamine is obtained, but if Hg ions are in the solution, NO is obtained (a paste of Hg_2SO_4 on the Hg).

In the electrolysis of a 0.3 normal NaCl solution, without diffusion, 5 per cent of oxygen is obtained. In alkaline solutions, ketones are reduced and in acid solutions are formed pinacones. Al can be deposited from ethyl bromide solutions. In the electrolysis of neutral solutions of $Na_2S_2O_3$ the tetrathionate is formed, but this can be prevented by the presence of $Hg(CN)_2$ or by brucine. Salts of Mn and of Cr are used as carriers in electrolytic oxidation. In electroplating, deposits are finer from dilute than from concentrated solutions, the presence of a colloid makes the crystals finer and the deposits are made pure by the introduction of substances to dissolve any oxide or hydroxide that might be formed: e.g., in plating Zn, H_2SO_4, KOH, NH_4Cl, and KCN are used.

4. **Current Density.**

In electroplating too high a current density makes the deposit go bad, due to an impoverishment of ions and the precipitation of oxide, hydroxide, or basic salt. Deposits are finely crystalline with high current density and coarsely crystalline with low current density. When a current of less than 1 millampere is passed between metal electrodes in distilled water, arborescent crystals are obtained.[5] With Fe as anode in sodium acetate acetic acid solutions, at low current density, ferrous acetate is formed and with high current density Fe is passive. Since current density is proportional to the rate of deposition, Al can be deposited as a metal from $AlCl_3Aq$ with such a current density (0.085 amp per square centimeter) that the rate of solution is less than the rate of precipitation.

A high current density is conducive to low electrode efficiency, because the H or Cl., e.g., which is deposited escapes before it comes into contact with any of the reacting electrolyte. Therefore, in the oxidation of $Cr_2(SO_4)_3$ to CrO_3, and in the preparation of iodoform, the anode is large and the cathode is small. In general, the effect of current density is that of mass action.

5. **Diffusion.**

In the deposition of metals a high current density causes an impoverishment of ions at the cathode and thereby causes the deposit to go bad. This impoverishment is prevented by means of stirring with CO_2, H_2, or with rotating cathode or anode. In the precipitation of Al, Tucker[6] uses a pasty solution of $AlCl_3$, 40°, C.D. = 0.085 amp per square centimeter, and a cathode of brass rotating at 15,000 r.p.m.

In many electrolytic processes the reaction at only one electrode is utilized and the reaction at the other is harmful. In the electrolysis of NaCl to form NaOH the caustic at the cathode is separated from the Cl at the anode by means of a diaphragm of Hg. Diaphragms should be very easily permeable to charged ions and should offer a high resistance to diffusion. In making iodoform, the CHI_3 at the anode is separated from the H at the cathode by means of porous porcelain in order to avoid reduction. In making NaClO, $CaCl_2$ or K_2CrO_4 is added to the electrolyte, giving a precipitate of CaO or $Cr(OH)_3$ at the cathode. This precipitate is a membrane which allows the passage of OH and Na ions, but prevents the diffusion of NaOCl to the cathode.

6. **Light.**[7]

Bancroft has shown that those changes which are produced in compounds by means of light can also be produced electrolytically. "Light is a low-voltage current." Also he has shown that the presence of light may affect the direction of a current of electricity and its incidental reactions. If a ray of light which acts as a reducing agent is allowed to fall upon one pole of an electrolytic cell and there brings about a reduction, we then have that pole functioning as the cathode of the cell, and an electric current flows through the cell from the unilluminated pole to the illuminated pole. AgBr is reduced by light which is rich in violet rays and Ag is set free. If

[5] Comptes Rendus, 130, 325, 1900.
[6] Trans. Am. El. Soc., p. 497, 15, 1908.
[7] Bancroft, *Jour. Phys. Chem.*, 1908, et seq.

AgBr is in close contact with the illuminated pole, Ag is deposited on that pole and it becomes the cathode.

If one AgBr electrode is dipped in erythrosine and then replaced in the KBr solution, the dyed electrode is the anode. These sensitizers are used with actinic cells (1) to intercept those rays of light which tend to work oppositely to that reaction which we wish to induce, and (2) the sensitizer is altered by light and yields a product which tends to accelerate the desired reaction.[8]

7. **E. M. F.**

Unless a certain difference of potential (decomposition voltage) exists between the anode and cathode, there will not be sufficient force to separate the ions. This decomposition voltage varies for different combinations of ions so that by careful regulation of the voltage we can select which ions to deposit. In electroplating, two ions are easily separated if the decomposition voltages of all the ions are exceeded and H has an intermediate decomposition voltage. Frequently it is noticeable when the same products are set free at the electrodes and at the same rate (equal current density), that there is obtained different reduction and oxidation products, varying with the voltage of the current. This voltage does not refer to decomposition voltage on anode or cathode, which varies with the distance apart of the electrodes without a change in the nature of the electrode products. The voltage which seems effective is the absolute voltage measured as the decomposition voltage of the electrode and the standard H electrode.

Alcohol is oxidized to acetaldehyde when the decomposition voltage of the anode and the H electrode is 0.7 volt to 1.0 volt; if a higher voltage is used it is oxidized to acetic acid. The decomposition of HF is higher than of HCl, and, therefore, in the oxidation of $Cr_2(SO_4)_3$, $MnSO_4$ and $CoSO_4$ solutions, by electrolysis, greater oxidation is obtained when HF is present. (Z. A. C., 33, 25, 1903.)

In reducing nitrobenzene with many different metals as cathode, various products and in various proportions are obtained, but the same products, azoxybenzene and aniline, are obtained when the cathode potential is kept constant. (Z. P. C., 47,418, 1904.) At platinum electrodes O_2 is formed at 1.08 volts and ozone is formed at 1.67 volts (voltage between anode and H electrode). At the cathode, reduction depends upon the voltage of the cathode compared to that of a H electrode in the corresponding electrolyte.

Counting the voltage of the cathode in a reversible H cell with platinized Pt electrodes as zero and then the "excess voltages" for the different cathodes are as follows:

Pd	−0.26 volt.
Pt	0.00 "
Fe	+0.03 "
Au	+0.05 "
Ag	+0.07 "
Ni	+0.14 "
Cu	+0.19 "
Al	+0.27 "
Pb	+0.36 "
Hg	+0.44 "

The greater force necessary to set free the H shows that these metals offer less accelerative influence in the change $H + H = H_2$. Therefore, these metals accelerate instead of retarding the actions of the H ion in the order of their excess voltages. The effects of these higher voltages are due in most cases to the specific nature of the electrodes and are probably catalytic effects. (See 8 and 9.)

8. **Nature and Concentration of Electrodes.**

Caffeine is reduced more quickly at a cathode of Hg than of Pb, although both metals possess the same cathode excess potential in pure acid. From nitrobenzene, with Cu cathode and NaOH, aniline is formed. With high current densities $KClO_3$ is only slightly reduced when the cathode is Pt, Pb, Zn, or Ni; moderately reduced with a Co cathode, and strongly reduced when the cathode is wrought iron. PbO_2 anodes oxidize $Cr_2(SO_4)_3$ with 80 per cent efficiency; Pb anodes with very slight efficiency. Aqueous KNO_3 is reduced 76 per cent with a Pt cathode, 15 per cent with a platinized Pt cathode and 97 per cent with Fe or Zn cathodes. A cathode of Fe reduces neutral $NaClO_3$ with 23 per cent efficiency, while Zn or Pt cathodes give practically no yield. (Z. E., 7,398.) $HNO_3 + H_2SO_4$ gives 100 per cent NH_2OH with a cathode of Hg, 40 per cent with a Pb cathode and 15 per cent with a Cu cathode. If the Cu cathode is covered with finely divided Cu then no NH_2OH is obtained, but a 100 per cent yield of NH_3 (Z. A. C., 31,289, 1902). If the Hg cathode is covered with Hg_2SO_4, insuring the presence of Hg ions, NO is formed. In the electrolysis of $HNO_3 + H_2SO_4$, if $CuSO_4$ is added, NH_3 is obtained quantitatively, but NH_3 is not obtained if instead of Cu we add Co, Ag, or Cd. When HNO_3 is electrolyzed with a Cu cathode, NH_3 is obtained, but NO is obtained when $Cu(NO_3)_2$ is present at the cathode. (Turrentine, 10,715, 1906.)

To remove brass from Fe tubing the whole is placed as anode in a bath of $NaNO_3Aq$, and the Fe remains passive and the brass dissolves away. (Burgess, *Trans.* Am. El. Soc., 1903, page 31.) To plate Ni upon a surface of Ni, the cathode Ni must first be made active by making it the cathode in another bath (acid solution) for a few minutes before use. (Snowden, J. P. C., 1905, page 399.) Na can be precipitated from aqueous solutions into Hg amalgam because of the slow reaction of Na amalgam with water. Fe and Ni in the amalgam make the reaction with water so rapid that no Na is precipitated.

When the anode is attackable, then the case is complicated by the presence of other compounds in the electrolyte.

9. **Catalytic Action.**

Above 90° cobaltic oxide acts catalytically in the electrolysis of chlorides, setting oxygen free. In 7 and 8 we have noticed that different metals as electrodes have different specific effects in electric reactions and that these effects are obtained without any apparent chemical action on the part of the electrodes. Such influences are probably catalytic. Bancroft[9] has shown that aromatic nitro compounds in acid solution are reduced to amines by Fe, Sn, Pb, and Cu as cathodes or when used chemically; and in alkaline solutions reduced to hydrazo compounds by Sn, Zn, and Pb chemically or electrolytically.

Ostwald[10] has said in regard to catalytic action in electrolysis that an ion first gives up its charge and then occur secondary reactions, and many different secondary reactions may occur.

Catalytic agents may retard some of these reactions and accelerate others.

Conclusion:

In conclusion we may say that reactions at electrodes differ from ordinary reactions in these ways:

(1) Energy is used instead of matter. The amount of substance used in electrochemical reductions and oxidations is small and its active principle is regenerated by electrical energy and used repeatedly.

(2) Localization of effect.

(3) Two dissimilar reactions occur simultaneously.

(4) The regulation of the reaction velocity is easy.

Bancroft has shown the identity of chemical reactions and electrode reactions, and has shown that the same variables affect the equilibrium in both cases. "The only specific action of the electric current is that it tends to set free anions at the anode and cations at the cathode. Reactions occur after the loss of the charge of electricity, and these reactions are ordinary chemical reactions."

Can National Professional Societies Be Exclusive and Representative?

The *Mining Magazine*, of London, edited by Mr. T. A. Rickard, prints in its March issue the following editorial, which is entitled "Mining and Metallurgical Society," but has a broader scope and more general interest:

"In April, 1908, the Mining and Metallurgical Society of America was organized, in part as a protest against the nondescript membership of the American Institute of Mining Engineers, and in part to stimulate the discussion of subjects expressly avoided by the Institute, and finally to promote the solidarity of the profession by frequent local meetings. It was intended on the one hand to avoid the duplication of facilities for publishing technical literature and on the other hand to stiffen the moral backbone of the profession by the crystallization of opinion in regard to the ethics and customs of mining engineers, metallurgists and geologists.

"The society started with a nucleus of representative men and at once reached a membership of 100, which on Jan. 1, 1910, had increased to 163, of whom 35 are geologists, 27 are professors, and 4 are editors. The other 97 are active mining and metallurgical practitioners. Of the several geographical divisions of the society formed with a view to local meetings, only two have evinced any life, namely, New York and San Francisco. At Philadelphia one or two small meetings have been held, but the members living near Chicago, Denver, Salt Lake, and similar centers of industry, have failed to organize for purposes of meeting. At New York and San Francisco the attendance has not exceeded an average of a dozen at each monthly meeting.

"Despite the smallness of attendance and the lack of co-operation between the general body of the members, the society has exerted a useful influence by expressing decided opinions in regard to company reports, the duties of consulting engineers, mine inspection, the Bureau of Mines, share speculation, and other matters having a vital bearing upon the business of mining. It is noteworthy that a deputation of the society, headed by the president, recently waited upon the stock-listing committee of the New York Stock Exchange and submitted the resolutions passed—at an earlier meeting of the society—with regard to the protection of mining investors. The resolution, and the members that submitted it, were well received. In another direction the society has also done good work, for the American Mining Congress has been pleased to ask the society to express its opinion and to formulate suggestions in regard to new laws regulating mine inspection.

"Thus it is apparent that the Mining and Metallurgical Society has won respect and has been able to exercise a beneficent influence. To complete this sketch of its career we may add that Mr. H. S. Munroe was the first president; he is succeeded by Mr. J. Parke Channing. No better men could have been selected as standard-bearers. The new officers include Mr. F. W Bradley as first vice-president and Mr. C. W. Goodale as second vice-president. Here also the excellence of selection is obvious. Mr. J. R. Finlay was the secretary and Mr. W. R. Ingalls was and remains the treasurer. As far as relates to the personality of its officers, the society is peculiarly fortunate.

"And yet the Mining and Metallurgical Society of America is a fiasco. It masquerades under a name far too comprehensive. No group of 160 men has the right to speak for the thousands of mining engineers, metallurgists, and geologists contributing at this time to the industrial development of the American continent. If there be not 1000 competent mining engineers and metallurgists worthy to rank as properly qualified practitioners, then the mines and smelters of the United States, Canada and Mexico are worse served than we had supposed. At the very inception of the organization it was proposed to issue a Blue Book of the elect, it is true that this proposal was killed, but apparently the spirit that animated the proposal, however well intentioned, lived to stimulate an exclusiveness wholly uncongenial to the main body of professional men in America.

"The society has failed to be representative because it has aimed to be exclusive.

"Soon after it was started a number of men applied for membership, but most of them were blackballed. Among these were two or three men as fit as any of those already enrolled. Apparently a few egregious blockheads deemed that they could place themselves on a pedestal by limiting the membership to the select group who became charter members before a severe selective process has been set to work. The scandal created by the refusal to admit several first-rate men into the society led to a revision of the by-laws, whereby the election of new members was transferred from the society as a whole to the executive council. Since then the proportion of applications rejected has been sensibly diminished, but the society has not recovered from the irritation produced by the crude effort to be select by blackballing all applicants. Only 27 new members were added in 1909, and 8 members resigned, including two or three men of the highest repute.

"We note that the retiring president referred to the failure to enlist the many professional men that should be members of a society arrogating a national name. He said: 'We have every reason to be proud of the character and attainments of our present members, but we have not, as yet, enrolled even a majority of the reputable and desirable engineers of the country.' Speaking without prejudice, as one fortunate enough to be within the pale, the present writer deems it proper to lay stress on the wholly un-American sentiment that has led this new society into a great blunder.

"The attempt of a fortuitous aggregation of individuals to sit in judgment on the members of a profession that includes thousands of men of varying education and occupation has failed utterly. In the effort to remedy the nondescript character of the American Institute membership, the new society went to the opposite extreme.

"The result is to indicate the difficulty of applying any known process of selection.

"Thus, in justice to the Institute, and particularly its veteran secretary, it must be confessed that the generous policy is the better of the two, simply because, humanly speaking, no tribunal exists by which character may be weighed, abilities appraised, and accomplishment valued. Men who are fit to-day may be unfit a year hence; the man who blundered a few years ago may be among the most efficient now; the personal equation still remains an insoluble problem.

"A mining engineer is the man who does the work of the mining engineer; whether he does that work well or ill it is for a jury of his peers to decide; but who is to select the jury? No self-constituted tribunal can assume disciplinary powers. Among the charter members of the Mining and Metallurgical Society are several whom we, in the exercise of a most fallible judgment, would exclude; among those refused admission are several with whom we would be proud to be associated.

"The lesson is one that should be learned by all engineering societies; for example, by our (British) Institution of Mining and Metallurgy.

"It is well enough to require certain qualities and to promote homogeneity as nearly as possible, but it is easy to err on the side of hypercritical requirement. Engineering societies arrogating national and even international guidance of world-wide professional activities must be representative before they dare to be exclusive.

"A professional organization is not a social club. An institution with only 1200 fully qualified members or a society of 160 is not warranted in the assumption that the one represents all the mining engineers, metallurgists and economic geologists of the British Empire, any more than the other can be permitted to assume to be spokesman for the thousands of professional men engaged in honest and efficient work on the continent of North America."

The Electrical Testing Laboratories and Electrochemistry.

By Clayton H. Sharp.

The electrical arrangements required for the conduct of any single electrochemical experiment are usually fairly simple and require from the laboratory in which they are conducted no elaborate equipment. There must be a supply of current of the proper strength and of the proper potential, arrangements for controlling and measuring the same, and the furnace or tank, or other vessel, containing the substance to which the electrical

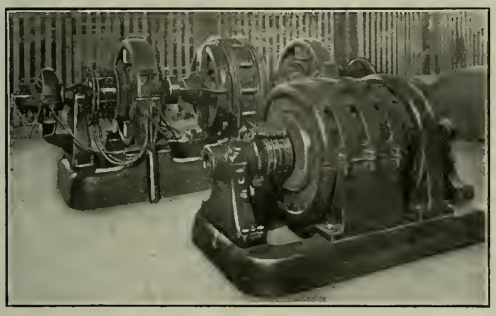

FIG. 1.—HARMONIC GENERATOR SET AND THREE-WIRE MOTOR GENERATOR.

energy is applied. When considering the laboratory equipment required for conducting electrochemical work in general, however, we are struck at once by the great range of the equipment and resources required to handle all classes of work. Taking the case of the supply of current alone, there must be available current of several thousand amperes at low voltage; current of several hundred amperes both direct and alternating at ordinary supply voltages, and current at very high tensions, but of limited intensity. From the one extreme of the heavy current of low voltage to the other of feeble current at high tension, it is necessary to be equipped to supply nearly any intermediate step.

Each step of an electrochemical process needs to be controlled by making accurate electrical measurements. This involves an equipment of electrical standards, and also a complete outfit of commercial electrical measuring instruments covering the entire range over which measurements may have to be made. The above requisites are the fundamental ones. When they are at hand and suitable space is also available, a laboratory may be said to be well equipped for carrying on electrochemical experiments of practically any kind, since in such research the energy-receiving device is usually of a special design, such as must be constructed by the experimenter in any case and cannot be provided for in advance. Laboratories in which facilities along the lines just outlined are available and in which the experimenter in electrochemistry may personally carry on such experiments as he desires, or may have them performed under his direction by the laboratory's testing force, are not so numerous as to make a description, in this place, of the equipment of such a one superfluous.

The main laboratory of the Electrical Testing Laboratories, being located in New York City, is within easy reach of a larger body probably of those interested in electrochemistry than would be the case if it were located at any other point in the United States. The plant is housed in a very substantial building, most of which is of fireproof construction, and which has a large stack, which formerly carried away the products of combustion of a battery of 14 steam boilers. This stack furnishes an excellent ventilating appliance. The points in the equipment of the laboratory which are of the most significance for electrochemical work will be described in much greater detail than those features which have no such immediate bearing, although they may be of great importance for other lines of electrical work. The description may fall under the general heads of the Supply of Current, the Standards and the Apparatus and Methods.

Supply of Current.

The supply of current is obtained from the New York Edison Company through underground cables. The main portion of the supply is furnished in the form of three-phase alternating current, 25 cycles and 6600 volts. The cables are capable of transmitting from the great Waterside Stations of the Edison company a large supply of energy in this form. Besides this, cable connection is had with the direct-current 120-240-volt service of the Edison company. Two cables furnishing this connection are taken from the street mains, while a third is connected directly to the end of one of the feeders of the three-wire system and consequently being a direct transmission from a substation equipped with rotary converters and storage battery furnishes current which is free from erratic fluctuations in voltage due to varied loads on the distributing mains. A total of 500 or 600 amp at 240 volts is available from this source.

In the ordinary operation of the laboratory the high-tension three-phase current is used for driving a 150-kw motor-generator which furnishes the requisite current for the life testing of incandescent lamps. The high-tension supply is also stepped down in a three-phase transformer, thus making available a supply of 25-cycle current at 220 volts. This may be used directly in experimental work and is useful also for driving motor-generators. The motor of the set for the life testing of incandescent lamps is wound for 6600 volts, while the generator is a three-phase, 60-cycle, 120-volt machine, from one phase of which the lift-test operations are carried on. The generator voltage is maintained very constant by a Tirrell regulator, supplemented by hand regulation through a sliding contact rheostat in series with the alternating-current helix in the regulator. Except at times of maximum life-test load a supply of 60-cycle current is available from this machine which is very useful in connection with electrochemical work.

The Edison direct-current service, besides being available directly for experimental work, is used to drive the elevator motor and other motors, to charge the storage batteries and to

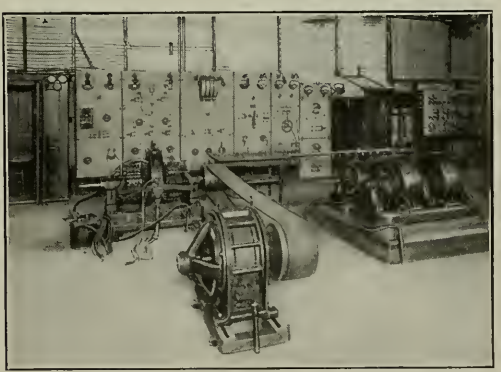

FIG. 2.—HEAVY-CURRENT DIRECT-CURRENT GENERATOR.

light the building. An additional three-wire service is furnished by a motor-generator of special construction, consisting of a 220-volt, 25-cycle induction motor of 50 hp rating, directly coupled to two direct-current generators, each rated at 120 volts and 15 kw. These machines are equipped with slip rings so that alternating current of approximately 37 cycles per second can be taken from them and so that their voltage can be controlled

by the use of Tirrell alternating-current regulators. In order to permit the use of this type of regulator each machine is equiped with a separate directly connected exciter. The very steady direct current at 120-240 volts furnished by this set is utilized chiefly for burning tantalum lamps on life test, it being a well-known fact that tantalum lamps have a somewhat uncertain life when operated on alternating-current circuits.

Two sources of direct current at low voltage are available. One of these is a set of four storage cells with an eight-hour discharge rating of 250 amp; these cells can be connected in series or parallel, as required, and are capable of delivering several thousand amperes for a short time. They are chiefly useful in connection with the calibration or standardization of instruments. Another source of very heavy currents is a double-commutator generator, which is belt-driven from an induction motor and the field of which is excited from a 120-volt circuit through a rheostat. Each side of the generator is rated to deliver 1500 amp at 8 volts. The sides may be put in series or parallel, so that 1500 amp at 16 volts are available, or 3000 amp at 8 volts. This is the normal rating of the machine. As high as 7000-amp currents have been taken from it without difficulty or distress, and the limit has not been reached. This machine is used at times for the calibration of large electrical

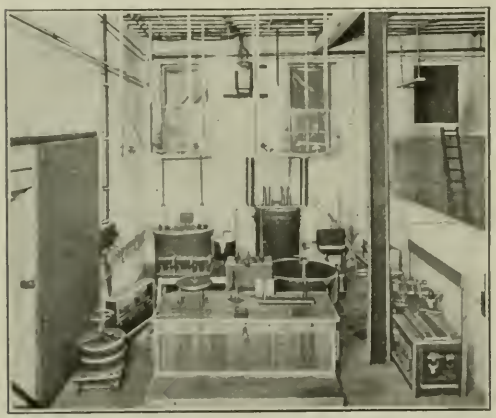

FIG. 3.—HIGH-TENSION LABORATORY. 250,000 VOLTS.

instruments or circuit-breakers, and when so used the terminals of the machine are short-circuited through the instrument and a standard manganin resistance. The current is controlled by varying the field current and consequently the voltage of the machine. Its utility in electrochemical work is manifest.

Heavy alternating currents are obtained by means of two step-down transformers, wound for 100 volts primary and 4 volts, 8 volts or 16 volts secondary. Each transformer is mounted on a truck so that it is readily portable, the truck carrying also a switchboard, by means of which the four sections of the secondary winding can be placed in series or in parallel. The normal rating of these transformers is 12 kw, so that they are capable of delivering continuously 3000 amp at 4 volts, 1500 amp at 8 volts or 750 amp at 16 volts. These two transformers can be operated in parallel or in series.

The equipment of storage batteries includes among others one battery of 70 cells with an eight-hour discharge rating of 60 amp; one battery of 70 cells with eight hour discharge rating of 30 amp; four batteries of 10 cells each of 30 amp; one battery of 70 cells of 7.5 amp, and 400 cells of 0.75 amp. For the purposes requiring a greater range of potential than is available from the batteries, namely, about 1000 volts, a set of five direct current generators is provided. These generators are driven by a common motor and each one is insulated from the earth and carries its own directly connected exciter. In series, these generators will supply direct current at 12,000 volts.

The supply of alternating current at high voltage is obtained from transformers. For voltages up to 6600 ordinary lighting transformers are used. For higher voltages there is available a transformer rated at 10 kw with 100-volt primary and four secondary terminals of 30,000 volts each, giving a total of

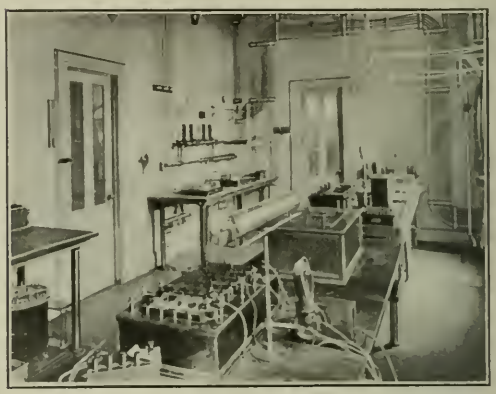

FIG. 4.—STANDARDIZING LABORATORY.

120,000 with the secondaries in series. There is also a transformer rated at 50 kw stepping from 220 volts to 250,000 volts. This last voltage seems high enough to meet all the present practical demands of testing and experimental work. The voltage of the secondary of the high-tension transformers is controlled by a variable-ratio auto-transformer in the primary circuit.

The main part of the work in which high tensions are required is involved in the inspections of high-tension insulators

FIG. 5.—APPARATUS FOR STANDARDIZING CURRENT TRANSFORMERS (UP TO 5000 AMP).

for long-distance transmission lines. These inspections are made in the insulator factories.

There are two other sources of alternating supply which are, however, chiefly interesting in connection with testing and standardizing work. One of these is a pair of alternators exactly alike, placed on the same bedplate. These machines may be coupled together or may be driven separately at any required

speed, three-step pulleys being employed for the wide variations in speed and motor control for the finer adjustments. They are of the revolving-field type with their armatures arranged so that they can be rotated by means of a worm through 180 electrical degrees. The particular value of this arrangement is in connection with tests of meters where power-factors, other than unity, are desired. For this purpose the current for the field coils of the meter is taken from one of the generators, usually with a step-down transformer, while the potential is taken from the other generator and any desired phase relation is obtained between the current and voltage by shifting the armatures.

The other set referred to consists of a direct-current motor having three alternators on the same shaft. The motor is wound for 120-240 volts to give a wide range of speed variation. The alternators have the numbers of their poles in the ratios of 1:3:5. Their armatures are wound to carry the same current. The armatures of the two generators having the largest number of poles can be rotated by means of a worm. This set is designed primarily to furnish alternating current of any required wave-form by the superposition on the fundamental of the third and fifth harmonics. The amplitude of these harmonics is controlled by the field rheostats, while their phase relations can be changed by moving their armatures. Apart from its usefulness for the purpose for which it is directly designed, this set, furnishing as it does the wide range of alternating frequencies up to 300 cycles per second, is a very practical one in connection with the testing work.

Standards.

With the introduction of new and simplified methods of measurement, the discovery of new materials, the adoption of new designs, and the establishment of the great national standardizing laboratories to which the question of the accuracy of standards can be referred, the making of electrical measurements of precision has been in recent years greatly simplified.

The fundamental standards which must be on hand for electrical work are those of electromotive force and resistance. It is desirable also to have suitable standards of capacity and of inductance. The universally accepted standards of electromotive force are the Clark cell and the Weston cadmium cell. Both of these types of cell are at hand. The advantage of

FIG. 6.—CHEMICAL LABORATORY.

having both types is that the accuracy of the standards can be determined with somewhat greater certainty if it is possible to check the two types against each other. The ratio of the electromotive force of the Weston normal cell to that of the Clark cell is known with very great accuracy and hence an intercheck of this kind is of considerable value. For practical work, the Clark cell is very little used. The Weston normal cell, i.e., the cadmium cell, with an excess of cadmium sulphate, forms the most desirable primary standard. It is found in the operation of the laboratory, however, that it is usually more convenient to use secondary standard cells having a zero temperature coefficient. Consequently, the cells manufactured by the Weston Electrical Instrument Company (in which the solution of cadmium sulphate is saturated at 4° C.) are in con-

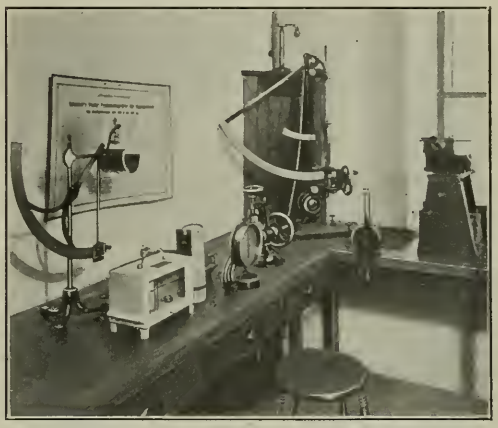

FIG. 7.—SCHOPPER TESTING MACHINE AND IVES' CALORIMETER IN PAPER LABORATORY.

siderable use. Cells of Hulett's reversible type, containing 1 per cent of sulphuric acid, are also in use and are very convenient working standards. These cells have the advantage that they are not damaged as a result of allowing them to deliver very considerable currents. Considerable success has been had also in the use of large reversible cadmium cells as working batteries for high resistance potentiometers. Two such cells of the dimensions given by Professor Hulett will deliver the current required by a 15,000-ohm potentiometer with remarkable constancy. The current may be interrupted when the potentiometer is not in use, and on closing the circuit little or no adjustment of the auxiliary resistance is necessary unless measurements of a considerable degree of refinement are to be made.

Standards of resistance of the Reichsanstalt type, having manganin as a resistance material, ranging in resistance from 100,000 ohms to 0.0001 ohm by steps of 1/10, are at hand in duplicate and triplicate, while oil-immersed standards of the Bureau of Standards type, ranging from 1 ohm to 100,000 ohms, are also used. While variations in some of these standards have at times been detected, yet they are in general so constant that they make the measurement of resistance exceedingly easy. In the measurement of current strength, the modern practice of using the method of the fall of potential through a manganin resistance is adopted, although a silver voltameter is also at hand. For purposes of measurement of this kind manganin resistances designed to have a maximum capability of dissipating heat are used. The largest of these is a resistance of 0.0001 ohm through which a current of 5000 amp can be passed continuously, and a still larger current for a short interval of time.

A standardized mica condenser serves as a standard of capacity while fixed and variable standards of inductance are also at hand.

For the measurement of temperature, there is available a set of four standard thermometers by Richter, in Berlin, covering the interval between zero and 400°, with 0.5° graduations and with the zero point and 100° point on each thermometer. For temperatures above this, a Callender platinum thermometer

is available. Special thermometers are used for calorimetric work.

In the department of photometry, the equipment of standards includes two Hefner lamps and two 10-cp pentane lamps, one of which is of American and the other of English manufacture. These lamps, however, are not referred to as standards in the ordinary course of photometric work. The real standards are constituted by a series of incandescent lamps carefully sea-

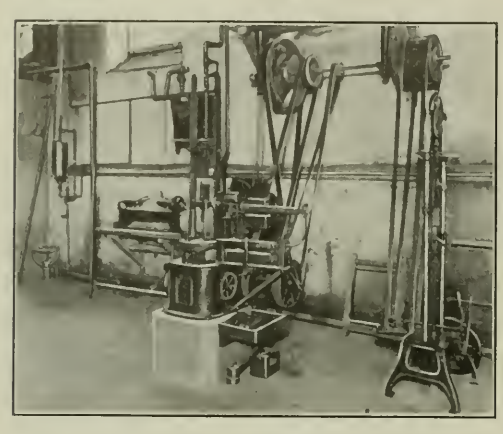

FIG. 8.—TESTING MACHINES.

soned and compared. The value of the unit of luminous intensity represented by these standards is the candle as recognized by the Bureau of Standards in Washington, by the National Physical Laboratory of England and by the Laboratorie Central d'Électricité in France. The greatest care is taken to avoid the possibility of any variation from the photometric standards once set, copies being continually made and compared with the older representatives of the standard and a frequent reference being made to the Bureau of Standards.

Incidentally to the above statement of the fundamental electrical and other standards used, the fact may be mentioned that the laboratories are entrusted with the periodic checking and certification of the accuracy of the standards of measurement of a number of the largest electricity supply companies in the country.

Apparatus and Methods.

In the measurements of electromotive force, the calibration of voltmeters, etc., the potentiometer and the standard cell are employed. Potentiometers both of the high-resistance and of the low-resistance type are used. For operations in which it is desirable to move the potentiometer from place to place the low-resistance type has the advantage that a sensitive pivoted galvanometer which is quite portable and which requires no leveling can be used with it. For precise measurements, the high-resistance potentiometer with a reflecting galvanometer is usually employed. Voltages higher than 1.5 are measured by the use of the volt box multiplier. For the high resistance potentiometer, the volt-boxes are of 100,000 to 200,000 ohms total resistance, for the low-resistance potentiometer, from 5,000 to 10,000 ohms, thereby insuring sufficient sensitiveness in working with the portable galvanometer.

For the measurement of alternating voltages, instruments of the soft-iron type, of the electrodynamometer type and of the electrostatic type are at hand. Of the latter type, mention may be made of a Ayrton Mather reflecting instrument giving full-scale deflection with 7 volts to 8 volts, a Kelvin multicellular electrostatic instrument specially equipped with a telescope and scale and reading to 150 volts, and a Westinghouse instrument reading directly to 120,000 volts, or operating in two lower ranges when one or both of two oil-insulated condensers are short-circuited. The last-named instrument has its moving parts entirely immersed in oil, and indicates high tensions in a very satisfactory way.

Evidently not all of these instruments can be standardized on direct current. The soft-iron instruments and also the electrodynamometers when used on currents of high frequency are subject to error. These are checked by the use of electrostatic instruments as transfer instruments from direct to alternating voltage. The Kelvin multicellular voltmeter with telescope and scale referred to above is the most important instrument for this purpose and when carefully used yields results of relatively high precision.

Ordinary resistance measurements are made on a decade type Wheatstone bridge. For precise work the bridge is used whenever possible by the substitution method. For instance, if another decade box is under investigation, and the 10 coils of 100 ohms each are being measured, the 100-ohm reference standard resistance is first measured by the bridge and then the 100-ohm coils in the box. By this method errors of the bridge are eliminated.

The measurement of low resistances is usually carried out by means of the Kelvin double bridge, though the fall of potential method with a potentiometer and standard resistance is sometimes employed. The Kelvin double bridge used is of the dial pattern with four decades. Among its uses is the measurement of the conductivity of copper and other materials. To assist in the measurement of the conductivity of copper, a set of copper standards of resistance have been prepared, one for each two sizes of the Brown & Sharp wire gage. These consist simply of pieces of copper wire, to the ends of which lugs for convenient attachment are securely sweated, and to which at a distance of about 1 m from each other potential terminals are permanently attached. The resistance of each of these standards is carefully measured at 20° C. by comparison with a manganin standard, the copper being immersed in an oil bath. Knowing the resistance of the standard, a table is prepared to show what length of copper wire of a given weight per unit length would have the same

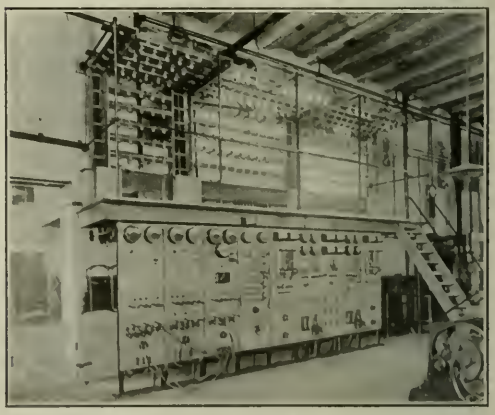

FIG. 9.—SWITCHBOARD AND TANTALUM LAMP LIFE TEST.

resistance as the standard, if its conductivity were 100 per cent in terms of Matthiessen's standard. The wire, the conductivity of which is to be determined, is cut to a length of exactly 120 cm, and is weighed. It is placed in series with the copper standard and knife edges are pressed upon it, giving potential connections at the distance apart which is indicated by the table. The bridge then reads percentage conductivity directly.

In the measurement of high resistances, such as that of insulating materials, in wire and cable tests, etc., a sensitive high-resistance d'Arsonval galvanometer is employed. The source of electromotive force is a special battery of 150 small accumulators installed on large rubber insulators in such a way as to insure immunity from grounds. Where the sensitive galvanometer method of measuring resistance is inadequate, the loss of charge method, using a Kelvin electrostatic voltmeter equipped with mirror, telescope and scale, to measure the potential, is employed.

An abundant supply of ammeters is on hand which can be calibrated accurately, using the standard resistances of low denomination and high-current carrying capacity which are constructed for the purpose.

A set of Kelvin balances, the largest of which will carry 1000 amp, is of particular use in connection wit hthe standardization of alternating-current ammeters and of series transformers for the measurement of current.

Use is made also of a bank of incandescent lamps as a means of standardizing small alternating-current ammeters. The voltage on the lamp-bank is measured by an alternating voltmeter of the electrodynamometer type which gives the same indications on both direct and alternating voltages. The lamp-bank is standardized on direct current and is brought to the same voltage on alternating current, whereby the value of the current is determined.

A supply of wattmeters is also on hand, including precision wattmeters of the Duddell-Mather and of the Westinghouse types. These can be standardized on direct current. Convenient apparatus is set up for the standardization of voltmeters, ammeters and wattmeters, including integrating wattmeters.

The important question of the precise determination of the ratio of transformation and of the phase displacement of current and potential transformers used in the measurement of large currents or high voltages has been gone into very thoroughly and a method developed and apparatus constructed for accomplishing the same. By this method the ratio of transformation is given as the ratio of two resistances and the phase angle is computed from the indication of an adjustable mutual inductance. The design and construction of nearly non-inductive manganin shunts of large current-carrying capacity has been involved and this has been successfully carried out in the laboratory work shop. The largest of these carries 5000 amp with water cooling and has a resistance of 0.0002 ohm. The phase angle between the current and the potential difference in this shunt has been measured and found to be 18 minutes.

By the use of transformers standardized as above the range of precision measurements in the laboratory is extended almost indefinitely.

A supply of apparatus, including among other things a Koepsel permeameter and a Picou permeameter, is on hand for the determination of the magnetic properties of iron and steel. The well-established ring method of testing iron with a ballistic d'Arsonval galvanometer, standardized by means of a mutual induction coil, is preferred for work of this character.

An oscillograph and a "point-by-point" apparatus for getting alternating wave forms are also set up and available for use.

A bomb calorimeter is used for determining the calorific values of coal, and a Junker's calorimeter for determining that of gas.

A small but well-equipped chemical laboratory is provided in which all of the ordinary analyses and other chemical operations required can be carried out. This is furnished with a hood and with gas, hot and cold water and compressed air. Opening from the chemical laboratory is a small balance room in which the balances are supported on a firm shelf.

A spectrophotometer of the best construction, and also an Ives' colorimeter, are available for use in such chemical and other tests as require a careful analysis of color.

The apparatus is also on hand for the accurate comparison of working thermometers with standards. This apparatus has been developed chiefly for the purpose of checking clinical thermometers along the lines pursued by the Bureau of Standards.

A series of machines by Schopper, Riehle and Olsen are on hand for testing the tensile strength of materials up to a maximum of 15,000 lb. This series will soon be supplemented by a machine for tensile and compression tests up to 200,000 lb., and also by one for torsional tests up to 240,000 inch-pounds.

A well-equipped photographic darkroom is also provided.

The laboratory for the measurement and testing of various sources of light is most complete. Its equipment includes a Matthews' arc photometer installed in a photometer room 70 ft. long and used for determining the mean spherical candle-power, the mean hemispherical candle-power and the distribution of light in a vertical plane, of arc lamps and of large gas lamps, such as are used in street lighting, etc. For the determination of mean spherical and mean hemispherical candle-power of large sources of light, there is also an integrating sphere 2 m in diameter constructed of sheet iron and conveniently arranged to give access to the interior and to fit it for practical use.

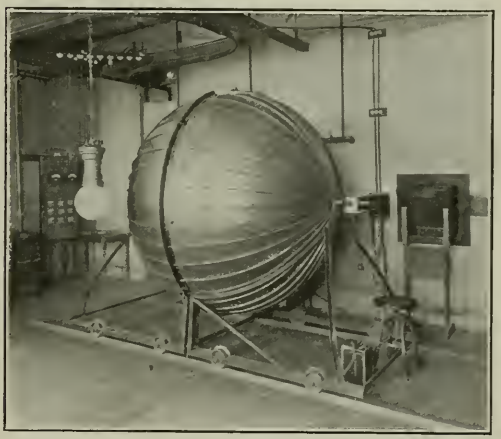

FIG. 10.—INTEGRATING PHOTOMETRIC SPHERE.

A photometer room is set aside chiefly for the photometry of gas lamps. This is equipped with the necessary gasometers, meters, pressure regulators, etc. The photometer track in this room is 5 m long. There is an arrangement of three very large mirrors placed on a frame which can be turned to any angle about a horizontal axis, by means of which the intensity of the light emitted at any vertical angle from a lamp is thrown on to the photometer disk. By the use of this apparatus the curve of vertical distribution of the intensity can be obtained without disturbing the lamp.

The standard photometer room is equipped with a long photometer bar of the Reichsanstalt pattern carrying a Lummer-Brodhun contrast photometer. The normal distance between lights in this photometric outfit is 5 m. The arrangements, however, are such that this can be varied at will. The electrical measurements are made by means of a potentiometer and standard cell. On this photometer, as on all of the others, the greatest attention is given to the question of screening the photometer disk from the influence of stray light, an important point which is too often overlooked in photometric work. The work of this room consists largely in the standardization of incandescent lamps as standards of luminous intensity. The lamps to be used for this purpose are carefully seasoned until

they reach the point at which the rate of change in candle-power is very slow. In the process of standardization their candle-power is read carefully by different observers on different days. In some cases the process of standardizing a lamp extends over some months. In this work, as in all the photometric work, the substitution method is followed, a set of standard lamps first being controlled against a comparison lamp, and afterwards the lamps to be standardized, which are then placed in the same receptacle and are measured by the

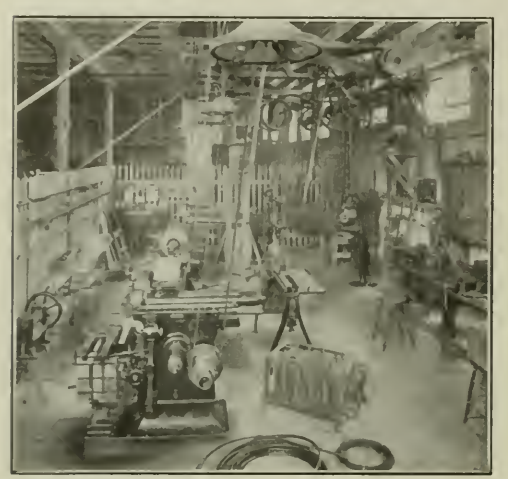

FIG. 11.—MACHINE SHOP.

same instruments as have been used in the case of the standard lamps. Several hundred such lamps are prepared and sold each year to lamp makers, users and photometrists generally.

A large part of the photometric work is incidental to very elaborate inspections and tests of incandescent lamps, which the laboratories are carrying on, and which cover many million lamps per year. The chief part of the inspectional work is carried on in the factories in which the lamps are made, but samples of the lamps so inspected are brought to the laboratories for purposes of a life test. These sample lamps are carefully read on industrial photometers and are put on racks to burn at their proper voltage to the nearest tenth of a volt. At approximately 100-hour intervals, they are removed and re-photometered, whereby their life history is determined. Some 3000 lamps can be life-tested simultaneously.

The industrial photometers, by the aid of which this work is performed, are a modified form of the photometers which are in use in lamp factories. They have been very greatly refined in details, so that they are capable of yielding results of relatively great precision. The Leeson star disk form of photometer is used in this class of work on account of its simplicity and on account of the convenience with which the operators can observe it.

In connection with the incandescent lamp work, there is a Matthews' integrating photometer for determining the mean spherical candle-power of incandescent lamps, and also an integrating sphere 30 in. in diameter which has been found to be a superior instrument for this purpose.

There are also various portable photometers which are found to be of the greatest value in the measurement of distribution of light from sources of large dimensions, in the measurement of mean spherical candle-power in connection with the spheres, and particularly in the measurement of the illumination in rooms, and of the candle-power of lamps on the street. A most convenient form of photometer for this purpose has been developed as the result of the experience so gained.

This laboratory is not without that most important feature of any large working laboratory, namely, a machine shop. Various machine tools of the best types are therein installed and are used for the repair of apparatus and for the construction of new apparatus as required.

A feature of the laboratory consists in a number of private rooms which can be rented by those wishing to conduct their own experiments. These rooms are supplied with water, gas, compressed air, etc., and with electrical connections to the main laboratory switchboard, whereby all electrical currents, both direct and alternating, can be obtained.

The uses to which these private rooms have been put are most varied, but more of the work which has been done has been of an electrochemical character than of any other. Among the work which has been done, bearing upon electrochemical research, has been the experimental development of new types of electric furnace, and by two different parties, on the fixation of atmospheric nitrogen. In the case of one of the latter the plant installed was of such a size as to give data on the industrial value of the process, involving the question of cost, etc. Experiments have also been made in the fusion of quartz for the production of silica vessels, and in the use of the electric furnace in annealing transformer plates. Many tests of primary and secondary batteries have been made. Experiments have been carried on looking to the development of new insulating materials, etc.

The equipment, of which the above is but a meagre description, is being added to continually as requirements indicate, the purpose being to maintain the laboratory in a high state of efficiency and to keep it abreast of all of the latest developments along its line of work.

Plans have been prepared for apparatus which will make a considerably larger supply of alternating current available for general laboratory work, and particularly for electrochemical work. This apparatus will consist of a step-down transformer in connection with an autotransformer whereby any required voltage can be obtained between 5 volts and 600 volts by steps of 5 volts. Its normal rating will be of 150 kva. The considerable supply of power furnished through this apparatus

FIG. 12.—INTERIOR OF PRIVATE LABORATORY.

will enable electrochemical experiments to be carried out on a fairly good scale.

It is hoped and believed that the Electrical Testing Laboratories will be an important factor in the future development of electrical science along the chemical lines as well as along the electrical engineering lines to which its attention has in the past been chiefly devoted, and in which it has received extended recognition and substantial encouragement from manufacturers, users, engineers, experimentalists and many others.

Causes of Non-Uniformity of Blast Furnace Operation.

BY EDWARD B. COOK.

The writer has felt for some time that there is not enough co-operation between scientific men engaged along mechanical and metallurgical lines and the operating men who are running the blast furnaces. The cause of this is misunderstanding. The practical man feels that the scientific man does not understand practical conditions, and that although many of the suggestions made are of value they are impracticable.

It is the object of this article to take up the items, one by one, given in Prof. J. W. Richards' article on blast-furnace operation, printed in this journal, January, 1910 (page 18), and also to discuss the chief difficulty in blast-furnace practice which is causing a great deal of trouble and loss of money. No new information is contained. It is simply a statement of the practical man's troubles and his point of view.

Composition of Ore, Flux and Fuel.

There can be no doubt that this is a matter of great importance and to-day it is usually well looked after. Even where numerous ores, frequently irregular, are used in a furnace, the manager insists on knowing what the ores are and is able to mix them in such a way that there is seldom much disturbance of the flux. At many places cokes varying greatly in ash and sulphur are used, and a fairly uniform iron made from them. There is more or less leeway in flux in a good-working furnace, i.e., the slag can vary 3 per cent or 4 per cent in acids without throwing off the iron, provided the condition does not continue too long.

It has been found helpful at some plants to have the blast-furnace chemist make a monthly report of his analysis of all the materials entering into the furnace throughout the month and make up a theoretical analysis of pig iron and slag, and compare these with the actual analyses from the furnace. This makes the laboratory an integral part of the furnace operation, and if the chemist's reports do not check closely with those of the furnace, he is under the necessity of making some explanation, and he cannot blame it on the sampler, as the sampler is under his direct charge.

It is found that the theoretical slag is usually 2 per cent lower in acids, i.e., silica and alumina, than the actual slag.

Size of Lump.

It is impracticable to keep all the material entering the furnace, using 2000 tons of raw material a day, free from rain and snow—that is, irregularities on account of weather conditions. It probably will always be impracticable, particularly with such a bulky material as coke.

This, however, is not as troublesome a condition as might be expected. Within the last year it has only proved of annoyance once at our plant, and then was a disturbing factor for three days. Water, of course, is of benefit, and is being added largely to the charges before entering the furnace, usually after the material is weighed.

The Western furnaces during the past year have used large quantities of water—in fact, equal to from 5 per cent to 10 per cent in weight of all the ore put into the furnace. The purpose of this is to keep the top of the furnace cool, and also to prevent the loss of fine ore. In some places this water is measured by meter, but oftener it is put in at random and varies greatly in amount. There is no objection, usually, to the water going into the furnace. The only objection is to the varying quantities of water in the raw material before it is weighed, and the consequent changing of the burden and flux of the furnace.

As a general proposition, it is advisable to have all the material going into the furnace broken to a uniform small size. It is, however, impracticable to break all of this material down by sledges, and there are many objections to breaking it with crushers. For instance, at a German plant I inquired of a director whether they did not break any of the material. He replied that 12 years ago they did, but it had been discontinued at that time in order to save flue dirt, and that occasionally they break down large ore with sledges, but most of the material went into the furnace in good-sized lump. Even the dense Swedish ores are charged in big lumps. In this country there have been several instances where furnaces would not work on small limestone, and it was found necessary to use large stone in order to prevent top slips.

On a furnace that is working well, material irregular in size can be used without seeming detriment. As a general proposition it is well to have stone broken down to 4-in. size, provided it can be screened afterward and the dust taken out. It is well to have hard magnetic ores, and hard ores of all kinds, crushed down small, provided the percentage of dust so formed is not excessive, for in many ores loss through dust on account of crushing will very quickly use up the saving to be gained in improved furnace work by better preparation of the ore.

In regard to size of coke, in the same day I have had one successful blast-furnace manager tell me he attributed his success to the use of small coke, and another man equally successful say that he attributed his success to the use of large-size coke.

One cause of great trouble in a blast furnace is the practical man's lack of knowledge of the fusible slag. It is remarkable how little is known about the presence of spinel in blast-furnace slags, and many furnace managers are in difficulty to-day on this account. Others are using a slag entirely too infusible, unable to contain much sulphur, and are making a good deal of bad iron in consequence. The justification for this lack of knowledge is that few of the blast-furnace men have had the advantages of scientific training, and even those that had, do not know where to go for detailed information in regard to slags.

Intervals of Charge.

There can be no doubt about the necessity of regular charging. We are, however, very much troubled with poor distribution, and although great advances have been made in the last six years, so that now there can be no doubt but that mechanically filled furnaces with revolving tops give as good distribution as the old hand-filled furnaces, still we feel that the distribution is not all that it should be.

The modern furnace is charged as continuously as possible to be consistent with good distribution, i.e., in order to get the best distribution, a certain number of pounds of coke or a certain number of pounds of ore, or both, must be lowered in the furnace at one time in order to give a proper thickness or layer on top of the furnace. Most furnaces are equipped with a recording instrument showing the gas pressure on the furnace top. It shows exactly when the furnace was filled, day and night, and is a great aid to the superintendent in obtaining regular charging. We will probably never attain absolutely continuously filled furnaces until we have some sort of revolving or stirring arrangement to give distribution, such as has been adopted in modern gas producers.

Running Out of Iron and Slag.

The writer has frequently heard of the continuous-running cinder notch, but has never seen one, either in this country or abroad, and certainly would not venture to put any in at a blast furnace which he was running. The reason for this attitude is that furnaces appear to accumulate in the hearth a certain amount of so-called "dirt," which is mostly fine coke—not consumed in the furnace—together with some graphite. The only way to get this material out of the furnace is to wash it out with the slag.

If a small cinder notch is used it is impossible to keep the furnace clean. If too large a cinder notch is used the furnace is kept clean by washing out this material, but there is a much larger loss of iron carried out of the furnace mechanically with the cinder.

The manager tries to compromise between these conditions and often changes the size of a monkey or cinder notch, according to the condition of the furnace. It is hardly likely that this mechanical difficulty of the ordinary blast furnace will ever be done away with.

In regard to tapping of iron, most large furnaces to-day are tapped every four hours, some of them every three hours. They are tapped at a regular time in this country.

There is one furnace in England, however, which is used as a mixer for the steel works, in that it is tapped for a ladle of iron whenever the steel works asks for it. This is a small furnace, and the condition could not be met with our present skill on big furnaces. It is essential that a body of iron of certain size be accumulated in the blast furnace or else the bottom builds up so that the furnace cannot be tapped. There is no slacking of the wind to flush, nor is there any slacking at cast, ordinarily, except to shut in the iron notch. This time of "shutting in" has been reduced to an average of 30 to 40 seconds. We have run one furnace for two weeks without even slacking the wind to shut in the furnace. We find, however, that there is danger of burning men in this practice and that there is very little detriment to the furnace by throwing off the wind for 30 seconds once in four hours.

Temperature of Blast.

Although equalizing stoves have been invented for a number of years, to the writer's knowledge they are only in use at two furnaces in the United States. The ordinary blast-furnace manager is not prepared to recommend the expenditure of the money required for this installation, and practically no owners are willing to make the expenditure, even when the blast-furnace mahager does recommend it.

Most managers attempt to keep the temperature of the blast fairly regular by regulating a cold-air mixing valve. This, however, has many objections, as frequently the air does not mix properly, and one side of the furnace is receiving much colder air than the other. Another idea is to work two stoves continuously on the furnace—and have only two stoves on gas—regulating the cold-blast valves of the two stoves on the furnace so as to maintain the temperature reasonably uniform.

The difficulty with all these devices is that the temperature cannot be maintained uniformly high, but is usually maintained uniformly low, and there is a great loss of heat units.

There is not nearly as much irregularity caused in a blast furnace by a variation of heats of 200° in one hour as would be supposed.

Furnaces run along for years and have their heats vary from 100° to 200° every hour without showing unusual irregularity as compared with those receiving regular heats.

In this country we have been unable to use high heats. The stove equipment is far below that of German practice, but most managers do not use what they have—whether on account of our coke and ores or lack of knowledge of blast-furnace construction, we have been unable to get our furnaces to do good work on heats as high as those used in Germany. Up to two years ago the successful manager was usually using not over 900° Fahr. To-day 1000° to 1100° is being used by many managers, but there are still a large percentage sticking to the low heats.

When in Germany I asked a blast-furnace director why he did not run his heats over 1475° Fahr. He replied that the furnace would not stand any higher heats, but stuck fast, and, indeed, it was necessary for him to use all cold air after each cast for half an hour to get the furnace to "move off," i.e., start to settle again.

In the East with magnetic ores higher heats are used, but even there there seems to be a limit of about 1200° except at certain times when the furnace turns cold. It will be a very great advantage to the blast-furnace business if someone can devise a furnace on which high heats can be used continuously.

Moisture of the Blast.

There can be no doubt but that the low moisture of the dry blast is the great value and that perfect uniformity is a second consideration. One blast-furnace manager regularly used steam in his air in irregular weather in order to keep the moisture entering the furnace uniform and to keep the furnace from sticking fast by getting too hot high up on low-moisture days. This, however, was unsatisfactory.

It is evident to the manager that irregular moisture, around 1 gr., is of very little importance, while moisture around 2 gr. makes a great deal of difference, so that although uniformity is of value, the main thing is *low* moisture.

In regard to keeping exactly the same weight of oxygen entering the furnace, this also is a refinement which at present we have not found any great necessity for. I know of several managers who varied the revolutions of their blowing engines in proportion to the temperature of the air, so as to deliver as nearly as possible the exact same weight of oxygen to the tuyeres, but this has always been discontinued after a certain length of time, and I do not know of anyone who is attempting to do it to-day. Blowing engines are carefully watched, however, and revolution counters used to make sure that the same number of revolutions are run hourly, also clock-speed recorders to show that the revolutions have been regular during the hour.

At our dry-blast furnace we have attempted to keep the temperature of the air entering the blowing engines regular as well as to keep the moisture regular. We have not, so far, been able to demonstrate that this regulation of the temperature is essential.

The writer does not wish to take the position that regularity as regards composition of material, size of lump, interval of charging, running out of iron and slag, temperature, moisture, and weight of blast are unnecessary and not worth the trouble of attempting, but the point to be made is that practically none of these things, as ordinarily cared for in an average plant, are interfering with fairly regular running and reasonable profits. There is, however, one particular feature which does materially and seriously interfere and which will now be considered.

Furnace Lines and Accumulations on the Bosh.

There is a saying among blast-furnace men that if a furnace is built right anybody can run her; if she is not built right nobody can—and the truth of the matter is that none of us know how to build one right.

There are certain things that have been developed—for instance, that it is not economical to attempt to burn over 4 lb. of coke per square foot of hearth area per minute, and that the furnace must be built of certain size of hearth in order to make the requisite tonnage.

From experience it has been found that it is not well to have too great velocity through the tuyeres—in fact, a velocity measured by a difference in pressure of 1 lb. is about right. It has also been determined that the economical height is somewhere between 85 ft. and 95 ft., but it is not known what is the proper height of the bosh or the proper angle, nor consequently the diameter of the bosh.

It is not necessary here to go into the lines in detail, nor devices for maintaining the lines at stock line, hearth, etc., except to say that there has been great improvement in recent years.

Accumulations on the Bosh.

In *Stahl und Eisen* Professor Osann speaks in his article on the dry blast of furnaces that do not run regularly, the usual cause being that the sectional area of the furnace has become lessened. This is exactly the trouble, and is the trouble which keeps the blast-furnace manager awake at nights and is responsible for his general uneasiness. This lessening of area is no longer due to the old high-melted scaffold, which troubled our fathers. On account of improved working conditions and

lower fuel consumption the high melted scaffold has practically disappeared and we seldom hear the word "scaffold" to-day.

The present lessening of area is about at the top of the bosh, sometimes just below the top of the bosh, and sometimes just above. A furnace in this condition is usually spoken of as having accumulations on the bosh or being a dirty furnace. Sometimes this condition happens in blowing-in, and the furnace is never able to do good work. At other times it will hardly be felt for the first year. Ordinarily, however, it occurs in from four to six months. It has been noticed again and again that a furnace will do very good work for four to six months and then will start to drop back in tonnage, and the fuel consumption will increase largely on account of the irregular settling, i.e., hanging and jumping.

The cause of this accumulation is not known. To be sure, bad lines or any mistake in running or charging seems to accentuate it. There is also a difference according to the material used in the furnace. For instance, there is a great deal more trouble of this kind with magnetic ores than there is with hematites. The material seems to be largely unreduced ore with more or less lime. Some managers blame it on their limestone, others on the quality of the ore used, and still others blame faulty distribution. These are the main causes advanced for furnaces where everything else is closely looked after. Of course, excessive velocity of wind through the tuyeres or some other mistake of this kind accentuates the trouble.

The trouble is world-wide, but is very much worse in some districts than in others. If this condition cannot be remedied, the furnace has to go out of blast or run on very irregular iron produced at excessive cost. If hematite ores are being used, it is not so difficult to clean the furnace, but with magnetic ores the trouble is frequently fatal, as the material, if by chance it comes off at once, is sure to bung up the hearth of the furnace. The cleaning process in any instance takes time and is a very expensive matter.

In the way of prevention, changing the lines of the bosh has been tried without much resulting benefit. Bosh jackets have been substituted for bosh plates, and *vice versa*—in fact, the blast-furnace managers keep wandering around in a circle as far as these things are concerned, always wanting what they have not got. There seems to be no way whatever to absolutely prevent the trouble. In England it is met at one plant by tuyeres on the bosh, which are used either part of the time or all the time. This, however, must greatly interfere with the zone of fusion in the furnace and cause high fuel consumption.

The men who are making the least "off" iron and having the least trouble to-day are those who are blowing slowly, keeping stove heats in reserve, and giving the furnace cleaning blanks every three or four days to prevent the formation of accumulations on the bosh.

Professor Osann suggests that the dry blast be used, together with controlling amounts of steam. Steam or water put into the tuyeres undoubtedly help to remove the accumulation, but dry blast will not do it.

As a preventative, dry blast is a great help, as it lowers the zone of fusion in the furnace and brings whatever accumulations there may be lower down. As a proof of dry blast's help in preventing this trouble, it is noticed that the dry-blast furnaces last year surpassed all other furnaces in average work. It is the writer's opinion that the same furnaces using the same material will take twice as long before being inconvenienced by accumulations on the bosh if dry blast is used, but dry blast alone will not remove the accumulations once formed.

While the furnace is "building"—that is, accumulating on the bosh—the work is excellent as the radiation from the bosh is reduced, the heat concentrated in the center of the furnace, and conditions are ideal. When the "building" has continued too long, however, irregular settling interferes with any kind of proper work in the furnace. If the bosh is kept clean by the use of short large tuyeres good work is impossible. The practice in Germany, and in some places here, is to try to adjust these conditions with the tuyeres, but results are not altogether satisfactory, and there is a certain period of high cost while the furnace is being cleaned.

The salvation of blast-furnace practice is going to be a furnace which can be blown out and put in again in a short time and without excessive expense. Mr. James Scott has done more than any other man in the United States along this line, as he has had the courage to put up a blast furnace containing only 12-in. of brick on the inwall. It can probably be put out and in again within two weeks and without great expense.

So far this furnace has worked very well, and is proving of particular interest, as it gives new information in regard to the loss by radiation and also in regard to the temperature of various zones in the stack. If this type of furnace is generally adopted there will be no longer any excuse for fighting poor working furnaces which contain dirt accumulations.

Blast-furnace managers to-day are not writing many articles —they are all too busy with their troubles to write about them, and for this reason there is not as rapid an improvement in blast-furnace practice as there should be. Many men are troubled with problems that have been solved by their neighbors.

In Germany the blast-furnace managers meet frequently and have papers on various subjects, by both theoretical and practical men. They also visit works in a body. It is to be hoped that something of the kind can eventually be attained in this country. In the meantime it is extremely desirable that someone should start to make scientific experiments in regard to blast-furnace lines. No private individual can afford to do this work. It would seem, however, a very good investment for the largest blast-furnace interests.

Pottstown, Pa.

Metallic Sodium from Fused Sodium Chloride.

BY C. F. CARRIER, JR.

During 1904, the author commenced a study of the art of separating metallic sodium. This investigation was carried on for two years and published in the form of a critical, bibliographic summary in ELECTROCHEMICAL AND METALLURGICAL INDUSTRY, v. 4: p. 442 and 475 (1906). In this same period the Castner sodium process was experimentally tested, and a proposed process of H. Becker thoroughly investigated on a laboratory scale. (*Electrochem. Ind.*, v. 2; p. 357 (1904) and *Zeit. f. Electrochemie*, v. 10, p. 568 (1904). The most important result of this latter investigation was that the temperature permissible in the electrolysis of fused caustic soda is considerably raised by the addition of sodium carbonate to the electrolyte.

As a result of these investigations and researches, it was concluded that the Castner process had attained about all that could be expected from the electrolysis of fused caustic soda. The history of the efforts to produce sodium by the electrolysis of fused sodium chloride did not offer any encouragement in that direction, but still the cheapness of the raw material and the directness of the process made it the most inviting line of attack.

The Acker process had demonstrated that sodium-lead alloy could be produced on a large scale with good efficiency by electrolyzing fused sodium chloride in the presence of a melted lead cathode. This suggested the possibility of using the preparation of the sodium-lead alloy as an intermediate step in the preparation of sodium. In 1903, Prof. J. W. Richards suggested to his students the possibility of refining metals by using the impure metal as a fused soluble anode in a fused electrolyte and plating the desired metal over to the cathode in the fused condition. The same idea has been advanced by

Borchers for the refining lead (*Zeit. f. Electrochemie*, v. 1; p. 13 (1894), and also by Hoopes for refining aluminum (U. S. P., No. 673,364 of 4-30-01).

From the above observations were evolved the general lines of a possible solution of the difficult problem of obtaining sodium from fused sodium chloride. If the Acker furnace were to be so modified that the lead-sodium alloy could be passed into a second compartment and there made a soluble anode in a fused electrolyte that would not consume the sodium, it would seem possible to recover the sodium at the cathode. This would make a furnace analagous to the Castner caustic cell, fused sodium chloride replacing the brine, melted lead performing the function of the mercury and the sodium being liberated in a fused bath instead of being allowed to react with water to form caustic.

This idea also forms the basis of the apparatus devised by E. A. Ashcroft (U. S. P. No. 788,506 and No. 801,199, *Trans.* Am. Electrochem. Soc. v. 9; p. 123, 1906, and *Electrochem. & Met. Ind.* v. 4; p. 145, 1906). The investigation to be described below was abandoned for financial reasons before entirely completed, but such a favorable state of development was reached that the conclusions are of value as well as of general interest, and are made public at this time through the courtesy of the Elmira Electrochemical Co.

Preliminary Trial.

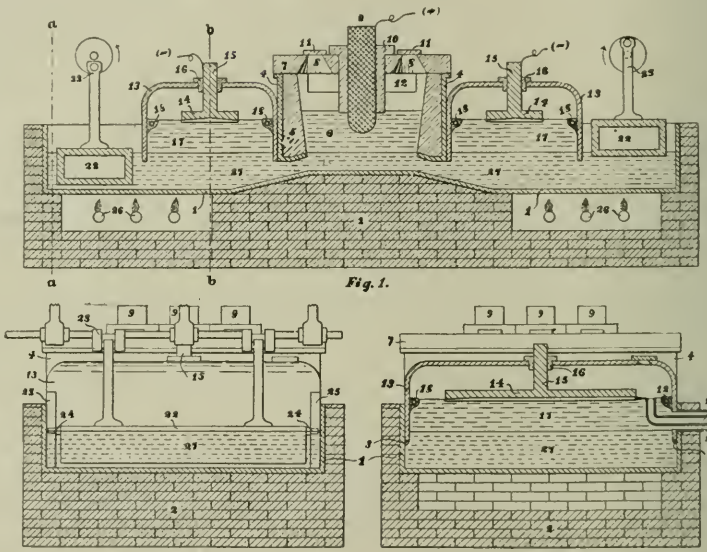
A small laboratory apparatus was constructed in the laboratory of the Technische Hochschule zu Karlsruhe in 1904. This consisted of a sheet iron box about 12 in. x 4 in. x 3 in. deep, divided into three compartments by sheet partitions reaching nearly to the bottom. Each compartment was provided with a sheet iron shell whose lower edge was about twice as far from the bottom of the box as the lower edges of the partitions, and which were of such size that about ¼ in. space was left between the shell and the sides of the compartment. This space was filled with Portland cement, leaving an opening beneath the partitions.

The box was mounted on a fulcrum and eccentric so that it could be rocked in the same manner as the Castner caustic cells. The bottom of the box was filled with sufficient melted lead to form seals below the partitions and a gas burner was provided to keep the contents melted. All three compartments were filled with melted caustic soda, the two end ones being the anode compartments and the middle one the cathode compartment. The capacity of the apparatus was about 50 amperes.

Only a few trials were made with this apparatus, for the results could not be conclusive either for or against. The cement fouled the electrolyte, causing objectionable foaming and unsatisfactory operation generally. Sodium was liberated at the cathode but from the conditions of the experiment, it would be difficult to prove whether the caustic in the anode compartments was the real source or not. Very little gas was evolved at the cathode, which is not the case in the simple electrolysis of fused caustic, therefore it was assumed that a portion at least of the sodium was being produced according to the theory of the process. It was, therefore, determined to test the process on a commercial scale and the above mentioned company was formed for the purpose of erecting and operating an experimental plant.

Electrical Equipment.

It is impracticable to treat fused sodium chloride on a small scale, therefore a dynamo of 1000 amp. capacity was secured, although in the light of experience 2000 amp. is to be preferred. The dynamo was seperately excited by means of a small 110-volt dynamo. Regulation was partly obtained by a speed controller on the motor driving the dynamo, but chiefly by regulation of the field of the exciter, in series with which was a rheostat and a bank of incandescent bulbs. In this manner the voltage could be varied from 2 to 16, the capacity being 10 kw. The main circuit was provided with a 1000-amp. ammeter and a voltmeter. There was also a shunt circuit with a capacity of 300 amp. and a corresponding ammeter. By means of a water-pipe rheostat, the amount of current passing through the cathode compartment could be regulated accord-



FIGS. 1, 2 AND 3.—PISTON TYPE FURNACE

ing to the efficiency of the operation of the anode compartment as will be explained below.

Piston Type Furnace.

This furnace was designed for 800 amp. capacity, allowing a margin for possible increase in the current density without overloading the generator. The general features of this type will be more clearly understood from the illustrations, Figs. 1-3, from U. S. P. No. 830,051, but some modifications were made in the experimental installation, which will be specially noted later. The apparatus will first be described as planned. The changes and reasons therefor will be described in detail, thus marking the progress of the research.

Fig. 1 is a longitudinal, vertical section. Figs. 2 and 3 transverse vertical sections on the lines *aa* and *bb* respectively in Fig. 1, looking to the right. A rectangular, cast-iron pan 1 is set in masonry 2. The other portions of the apparatus up to 18 inclusive are supported within the pan by shoulders 3. Over the raised portion of the pan is located the anode compartment, enclosed by a cast-iron frame 4 which is lined with fire brick 5, which will withstand the fused electrolyte 6.

The cover 7 consists of a cast-iron frame filled with a fireclay concrete composed of broken brick, fire clay, and a little cement. Feed holes 8 and openings for the graphite anodes 9

are also provided. To protect the anodes from oxidation, they are protected by means of earthenware sleeves 10. The feed holes are covered with simple slabs 11. A port 12 located at the back of the anode compartment carries off the gases formed. The two cathode compartments are in the form of an inverted, rectangular, cast iron box, opening downward, forming a sort of bell 13. The cathode proper is an iron plate 14 supported by heavy lugs 15, which are insulated from the bell by an insulating sleeve 16.

To prevent the current from flowing from the cathode to the bell, a portion of the electrolyte 17, is solidified by means of the cooling pipe 18, through which water is circulated. The pipe 19 for removing the metal produced is insulated from the other parts of the cathode compartment. The melted lead cathode 27 is circulated by means of the pistons or floats 22 which are raised and lowered alternately by means of the cranks 23. (To reduce the cost of construction, the pistons in the experimental furnace were operated by a walking beam instead of by cranks.)

As already noted, the operation of the furnace is analogous to the Castner caustic cell. The fused sodium chloride is decomposed by the current yielding chlorine at the anode and lead-sodium alloy at the cathode. The circulation of the alloy carries the sodium to the cathode compartment where it is dissolved out of the alloy by the ions liberated at the surface of the alloy which here acts as anode, and the sodium is liberated at the cathode. The electrolyte in the cathode compartment is not decomposed at all ultimately, simply serving as a medium for the current to transport the sodium from the anode to the cathode. The circulation of the lead is facilitated by the raised bottom of the pan. The constriction of the path of flow increases the velocity of flow beneath the anode compartment and thus gives a positive transfer of the alloy from one compartment to the other.

In the furnace as constructed the pan 2 was 5 ft. long by 3 ft. wide. The anode compartment 28 in. x 13 in. x 9 in. high (internal). The cathode compartment 28 in. x 8 in. x 4 in. high (internal). Pistons 26 in. x 7 in. x 4 in. (external). Stroke 2½ in. Displacement, 450 cu. in. per stroke. The anodes consisted of 5¼ in. diameter by 4 in. long heads screwed onto 3 in. diameter rods, which in turn were screwed into a heavy cast iron head to which the cables were attached. There being three such heads, the total anode surface parallel to the cathode was about 420 sq. cm. (65 sq. in.). The cathode surface was about 2350 sq. cm (364 sq. in.). (This ratio is too large. In practice the cathode surface should not be any larger than the anode surface than can be helped.)

Mr. Acker states 295 amp. per sq. dm. as the current density at the anode in his furnace. The density in this furnace will be 190 amp per sq. dm. using 800 amp and and 235 amp per sq. dm., using 1000 amp. There is a maximum limit to the current density on graphite anodes in a fused bath of sodium chloride. In one experiment using 800 amp. on two of the above heads, a current density of about 300 amp. per sq. dm., it was found that the graphite was very rapidly corroded.

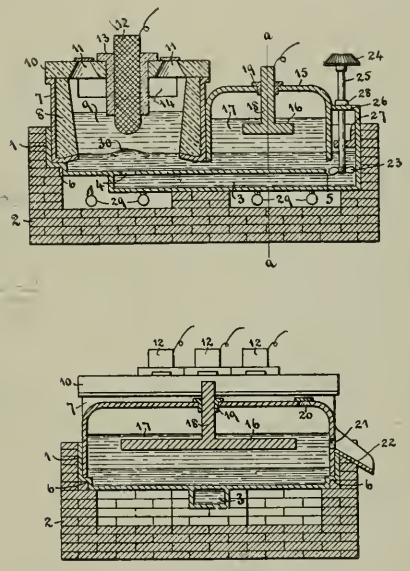
The gas burners were made on the principle of the Bunsen burner, on a greatly magnified scale. The gas supply tube was ¾ in. diameter and the outer tube 3 in. diameter by 24 in. long. The air was supplied by a fan. With natural gas, the whole furnace could readily be heated to a full red heat.

The piston type of furnace was only operated for a short time and not being successful was soon abandoned for the following reasons: (a) Excessive radiation loss: It will readily be seen from the illustration and description that the superficial area covered was comparatively large. The gas burners were only intended to heat up the furnace on starting, the heat being afterward maintained by the electric current, but it will be noted that while the area of the anode compartment, where the greater part of the heat is generated, is only 364 sq. in., the total area of the furnace is about 15 sq. ft. This loss alone was sufficient to kill the commercial possibilities of the furnace, but even greater difficulties developed.

(b): The piston circulation itself was a total failure. It being impossible to make a tight joint between the piston and the sides of the pan, a narrow rim was left which exposed a strip of the surface of the red hot lead. The melting point of litharge is above the temperature of the lead in the furnace and therefore it solidified in the space between the pistons and the side. The solid crust was lifted at each elevation of the piston, exposing a fresh surface of lead, until finally so much litharge had accumulated that the apparatus was brought to a standstill. Reciprocal circulation is also not recommended, as the reversal of the flow makes it impossible to obtain the desired velocity of flow under the anode compartment. It requires a strong, positive flow to maintain a clean metal surface at the cathode and this is more readily obtained by means of the improved furnace described below.

Continuous-Flow Furnace.

To overcome the difficulties mentioned above, an entirely new type of furnace was constructed. The piston circula-



FIGS. 4 AND 5.—CONTINUOUS-FLOW FURNACE.

tion was abandoned, thus rendering it possible to make the furnace more compact, with a corresponding reduction in the radiation loss. Continuous circulation was substituted for the reciprocating movement in the piston type. The general features will be readily understood from Fig. No. 4 and No. 5, from U. S. P. No. 859,431 of 7-9-07.

Fig. No. 4 is a longitudinal, vertical section and Fig. No. 5 is a transverse, vertical section on the line *aa* in Fig. No. 4. The cast-iron pan 1 is set in masonry 2. On the under side of the pan, and cast with it, is a longitudinal compartment 3. communicating with the pan through the circular openings 4 and 5. This forms a return passageway for the fused lead. The opening 4 is arranged axially with one of the anode heads and each anode head has a corresponding opening from the lead conduit. The remaining portions of the apparatus are supported within the pan by means of the lugs 6. The anode and cathode compartments are constructed in the same manner as described under the piston type.

At the end of the apparatus, beyond the cathode compart-

ment, is located the circulating device. This consists of the screw propeller 23, which is rotated in the opening 5 leading into the compartment or passage 3, by means of any suitable power-transmitting device, such as the gear 24. The same gas burners were used as in the piston furnace. The general action is the same as already described for the piston type.

Some small changes were made in the construction which do not exactly correspond with the figures given in this article. Two anode heads were used instead of three, the dimensions being the same as already given. The charging opening was in the front instead of in the top. The anode surface parallel to the cathode was 280 sq. cm. (43 sq. in.) and the cathode area about 1560 sq. cm. (242 sq. in.). On the basis of 800 amp. for the piston furnace, the new furnace was rated at 500 to 550 amp., but was found afterward to work better at a higher density, 600 to 700 amp. being usually used.

About 1400 lb. of lead were required to fill the furnace up to the seals under the edges of the compartments. The circulation was efficiently accomplished by means of a cast-iron propeller 4 in. in diameter, revolving 600 per minute. While the desired vigorous, positive circulation was readily obtained, this arrangement is not recommended for practical operation owing to the frail nature of the propeller. A tangential pump would work equally well and could be made sufficiently massive to withstand the rough usage involved in pumping red hot lead.

The great advantage of this type over the one abandoned rests in the circulation of the melted lead cathode. The strong current of fluid metal rises through the openings beneath the anode, forming a sort of mound on the surface, from which the flow radiates in all directions.

In this manner the surface of the cathode is kept perfectly clean, which is quite essential to the success of the operation. If this is not done, a difficultly fusible layer will coat over the cathode and abnormally raise the resistance of the electrolyte. This layer contains graphite dust torn away from the anode and the difficultly fusible impurities in the salt, as sulfate of lime. In time this layer, which is in a pasty condition, will stop the action of the furnace.

If, however, the circulation is accomplished as described above, the strong radial currents will carry the impurities to the sides of the compartment, where they will accumulate in a thick layer, which may be removed from time to time. In experiments with the piston furnace, where the circulation was weak, the operation was several times brought to a halt by this accumulation spreading over the entire cathode surface.

In starting, the furnace was first heated to a full red heat by means of the natural gas burners. This heat is not sufficient to melt the salt which is accomplished as described by Acker, *Trans.* Am. Electrochem. Soc., v. 1, p. 169 (1902). This consists in passing a strong current through a resistor until sufficient melted salt has been formed so that the electrolyte can carry the current. The resistors were ¾ in. or 1 in. diameter carbons, about 3 in. long, driven into the face of the anode blocks.

The resistors were heated to a bright red heat and the salt piled around them. Two resistors were usually used, one on each anode head. The 1 in. x 3 in. rods would carry 400 to 500 amp. at 4 to 5 volts and the ¾ in. x 3 in. rods, 300 to 400 amp. at 5 to 6 volts. After a time a pool of melted salt will form.

The resistors may then be broken off and the current started through the electrolyte. It is essential that the graphite anode be red hot before the resistors are broken off, for the melted salt will not "wet" the cool graphite surfaces; or in other words a thin layer of solid salt forms on the cold graphite and being a non conductor no contact can be obtained.

The preparation of the original bath, especially in experimental work, is facilitated by using a mixed electrolyte instead of the pure salt. A mixture of 3 molecules sodium chloride, 3 molecules potassium chloride and 2 molecules of calcium chloride melts readily at a red heat and will yield almost pure sodium on electrolysis, a small percentage of potassium being liberated with the sodium, but no calcium. After the current has once been started through the electrolyte, only salt need be added for this purpose only the very purest commercial salt obtainable is to be used, as the impurities form the infusible material mentioned above, which has to be removed. Mined rock salt is usually the best.

The furnace as described above may be used in the preparation of free metallic sodium or in the preparation of sodium compounds which ordinarily involve the use of metallic sodium at high temperatures. If sodium is desired, the electrolyte in the cathode compartment must be of such nature that it will not be decomposed by sodium at a full red heat.

As the present commercial process for obtaining sodium is based on the liberation of the metal in a fused bath of caustic soda, this compound was naturally the first one selected as the electrolyte for the cathode compartment. It was then a matter of considerable surprise when it was found impossible to obtain any trace whatsoever of sodium when the attempt was made. It was first thought that the fused caustic still held some last traces of moisture even at a red heat, but in this case there should have been at least a liberation of hydrogen. The electrolyte simply laid dead in the furnace and not a bubble or a globule of metal was formed to show that 400 to 600 amperes were being passed through.

The writer is not prepared to state positively that it is impossible to liberate sodium from fused caustic soda at 700 to 900° when the anode is soluble and contains sodium, but the indications from these experiments are that such is the case. The electrolyte was not wholly protected from the action of the air and it is possible that sodium reacted with caustic at this temperature to form a suboxidized compound, which took up oxygen from the air. However, it was thought best to avoid the presence of oxygen in the electrolyte.

As pure sodium chloride is so difficult to melt, the cathode compartment was filled with the same mixed chloride bath described above for use in starting the fusion in the anode compartment. As soon as the lead cathode had had an opportunity to take up sufficient sodium to supply the sodium required for the soluble anode, the current was started through the cathode compartment and regulated by the water rheostat so that only 75 per cent of the total would be acting in that comparment. As soon as the current is started the globules of metallic sodium begin to gather on the surface of the electrolyte.

The conditions under which the experiments were carried out were such that it was impossible to continue a single continuous experiment for a sufficiently long period to gain any reliable data on the ampere efficiency and for the same reason no fully satisfactory method of removing the red hot sodium was devised. It might be safe to assume that the ampere hour efficiency would equal the 93 per cent claimed for the Acker furnace (*Trans.* Am. Electrochem. Soc., v. 1, p. 171, 1902), but as some sodium is lost in removal from the furnace, 80 per cent was assumed as the basis of commercial calculations. The voltage was 6 to 8 volts using 500 to 700 amp. The experiments were finally stopped for financial reasons.

A few experiments were also made on the preparation of sodium compounds instead of the metal. Two important compounds requiring the free metal in their preparation are sodium peroxide and sodium cyanide. It was hoped that by liberating the sodium in a fused bath of caustic in the presence of air at a bright red heat that both the caustic and the sodium produced would be converted into a mixture of sodium oxide and sodium peroxide which by further heating in air could be entirely converted into the peroxide. Sodium nitrate was also used as an oxidizing agent in some of the experiments.

No conclusive results were obtained but it was found that the percentage of sodium oxide in the bath increased as the experiment progressed and the product would liberate oxygen

when placed in water. This product was so impure, however, that it was feared that it would not be able to compete with the high-grade material made from the previously prepared sodium.

It was impossible for reasons stated to carry the experiments further but it had been demonstrated that it was possible to produce sodium compounds by electrolysis in a fused bath with a soluble anode containing sodium, the bath being capable of uniting with sodium to form the desired compound. It is to be noted that these compounds cannot be prepared from lead-sodium alloy and reacting upon this with similar reagents, the method described being equivalent to the use of free sodium while the lead-sodium alloy is not.

This is due to the fact that the formation of the alloy is strongly exothermic and therefore a corresponding amount of energy is required to liberate the sodium from the lead before it can react. In brief, it is possible by this method to produce compounds of sodium ordinarily requiring the use of previously prepared sodium, without the expensive operation of obtaining the metal in ingot form.

In conclusion, it may be said that while these experiments left the problem in a partly developed condition, they fully demonstrated the possibility of preparing both metallic sodium and sodium derivatives along the lines described. With the experience gained, it would be possible to modify the apparatus as suggested above and complete the demonstration of the commercial feasibility of the processes, but no further funds being available the work had to be abandoned.

Temperature Coefficients of Resistance of Resistors.

Since nickel and nickel-chrome (the latter, for instance, under the trade name nichrome) are often used as resistors for electric heating or electric furnace work, the measurements of their temperature coefficients of resistance, as given by A. A. Somerville in a recent American Physical Society paper, should be of interest. (See *Physical Review*, February, page 268.)

Four materials were studied—nickel and nichrome, two good furnace wires, inasmuch as they do not oxidize readily; and tungsten and molybdenum, which must be protected from oxygen when heated. The nickel and nichrome curves are very similar in shape, but the coefficient of the former is 20 times that of the latter. The coefficients in either case are relatively small between 400° C. and 1000° C. as compared with the coefficients outside these limits. (Unfortunately, the exact numerical figures are not given.) The tungsten and molybdenum curves are slightly convex toward the temperature axis. The coefficients are large—1 ohm of molybdenum at 0° C. measuring 5.7 ohms at 1000° C. and 1 ohm of tungsten at 0° C. measuring 6.9 ohms at 1000° C.

Silica Standards of Length.

Silica standards of length are quite a novelty. As mentioned in the recent annual report of the (Brit.) National Physical Laboratory, careful experiments have demonstrated that silica is superior to glass as to thermal hysteresis, the coefficients per degree Centigrade being: Silica, from 0.5 to 1; Jena glass, 59^{III}, 2.7; Jena glass, 16^{III}, 3.5, all expressed in 10^{-8} units. The 1-m silica standard of the National Physical Laboratory is a tube supplied by the Thermal Syndicate, 2 cm in diameter, having half disks fused into its ends.

The difficulty of getting good defining lines on the silica has been overcome. Ordinary scratches chipped off in a day or two, and could not be seen when the tube was immersed in water. The ends have, therefore, been platinized, but on the lower surface; the graduation is cut through the platinum film into the silica, and the protecting glass cover rests against the lower platinized surface. The reading from above is, therefore, not affected by any tilt in the cover glass.

High-Temperature Gas Thermometry and Its Present Limitations.

By Arthur L. Day.

The measurement of temperature is different from most ordinary measurements. There is no temperature unit corresponding to a foot rule or meter stick which can be applied successively to measure an unknown temperature as we would measure the height of a room. Two temperatures of 1° cannot be combined in any way to give a temperature of 2°. Temperature measurement is, therefore, wholly a matter of arbitrary definition, of selecting some convenient phenomenon like the expansion of gas which varies continuously and uniformly (as nearly as possible) with temperature changes, of providing convenient arbitrary units of subdivision and then of observing its behavior under the same conditions which surround the unknown body whose temperature is desired. The expansion of hydrogen has been established by international agreement as our fundamental measure of temperature. The gas thermometer is, therefore, now the standard thermometer in terms of which all temperatures are expressed.

The theoretical interest in gas thermometry centers about the quantitative relation existing between the increase in the temperature of the gas at constant pressure or volume and the quantity of heat required to produce it. It is a somewhat inaccessible question by reason of the difficulty of approaching it experimentally with the required accuracy. Although the amount of the expansion of gases is more closely proportional to the quantity of heat applied than that of other substances, no strictly "perfect gas," in this sense, has been found.

The amount of the divergence in the case of nitrogen, which has a greater range of practical utility than other gases thus far studied, is of the order of magnitude of a single degree of 1100° C., and the uncertainty in this correction factor is probably smaller than the observation error of a practical gas thermometer in the present stage of its development. For this reason these theoretical considerations, which have been admirably treated by Buckingham in a paper, "On the Establishment of the Thermodynamic Scale of Temperature by Means of the Constant Pressure Thermometer" (*Bulletin* Bureau of Standards, 3, 237, 1907), do not seriously affect the definition of an accurate and practical high-temperature scale by means of the gas law.

On the other hand, there is no denying the fact that a great deal still remains to be done upon the experimental side before the steadily advancing requirements of both science and industry in the matter of a trustworthy temperature scale of sufficient accuracy, and even more particularly, of sufficient range, can be satisfied. It is no disparagement of the present system of temperature definition to say that the gas thermometer itself is a complicated and cumbersome instrument to use in any of the forms which have hitherto been devised, and possesses limitations both of range and of accuracy which are difficult to overcome.

One consequence of this, particularly in the region of high-temperature measurements, is that temperatures easily come to be regarded with unwarranted confidence in the hands of those who have never acquired a first-hand knowledge of these limiting conditions. This has been further facilitated by the comparative ease with which relative measurements of temperature can be made, even in the more inaccessible parts of the scale, with the thermoelement and the resistance thermometer. These devices are sensitive to temperature differences of the order of magnitude of 0.01° throughout their entire range, but they are dependent absolutely upon fundamental measurements with the gas thermometer for their evaluation in terms of the generally accepted degree Centigrade.

It is sufficiently obvious, though often carelessly overlooked, that no method of temperature measurement, however sensitive or adaptable it may be, can yield temperatures of greater abso-

lute accuracy than the system in terms of which those temperatures are defined. With the gas thermometer as our basis of definition, therefore, we shall know our temperatures with just the certainty which it is able to furnish and no more. There is, to be sure, some justification for expressing the results of thermoelectric or resistance measurements in units smaller than the errors of the fundamental scale, where only comparative measurement is involved, but such measurements must not be allowed to escape from this limitation.

It is not the purpose of the present article to discuss the general problem of thermometry or the particular advantages of one system of thermometric measurement over another in laboratory or industrial practice, but merely to speak very briefly of some of the work which has been done in recent years to increase the range and accuracy of the temperature scale upon which the various devices for measuring high temperatures depend for their calibration. Neither is it necessary in so brief a review to include any discussion of the relative theoretical merit or experimental practicability of the constant-volume and constant-pressure methods of gas thermometry. The reader will find it in Buckingham's paper already mentioned, as well as in earlier discussions to which he refers. The choice of the one or the other method is likely to be governed by the taste or predilection rather than by the necessities of the individual experimenter. Neither system possesses decided advantages over the other. All the recent measurements (including all those referred to in this paper) have been made with the constant-volume system.

By international agreement and nearly universal practice, two fixed temperatures are accepted as the basis of the modern temperature scale, the melting point of pure ice and the boiling point of pure water, both at normal atmospheric pressure (760 mm of mercury). The interval included between these two temperatures is subdivided into 100 parts by measuring the constant volume expansion of hydrogen from an initial pressure of 1 m of mercury throughout this interval.

The actual determination of these intervals or degrees Centigrade was made by Chappuis at the Bureau International du Poids et Mesures at Paris in 1888, and is a work of such extraordinary painstaking character in most particulars that no investigation has found it necessary to repeat it since that time. The probable accuracy of the individual degrees thus determined, i.e., of the international scale of temperatures between 0 and 100°, is stated by Chappuis to be 0.002°.[1]

To extend the scale beyond these limits in either direction it is (theoretically) only necessary to continue the measurement of the expansion of hydrogen, under the same conditions, down to or up to any desired temperature. In practice, this procedure encounters various experimental difficulties which increase rather rapidly as we get further away from the temperatures of everyday life.

These experimental difficulties serve to place definite limits upon the accuracy of temperature measurements at present attainable in different parts of the field, of which it is important to obtain a clear idea in order to be able to form a sound judgment of the probable significance of measurements at widely different temperatures. If we are told, for example, that a solution boils at 90.27°, we recognize that this accuracy is entirely practicable. If, on the other hand, platinum is said to melt at 1755.46°, it is of advantage to know that the last two figures are wholly without significance and the fourth is uncertain.

There is another reason for being especially explicit upon this point, for very few men in this country have ever made the laboratory acquaintance of the gas thermometer.[2] In its modern form the constant-volume instrument includes five principal features which will be briefly considered with particular reference to the limitations which they severally impose upon the accuracy of high temperature measurements: The gas (1) is contained in an impervious vessel or bulb (2) which is heated in an electric furnace (3) arranged to provide the utmost attainable uniformity of temperature about the bulb at all temperatures. A mercury manometer (4) measures the gas pressure within the bulb, and thermoelements (5) are used to transfer the gas thermometer temperature to standard melting points for general application. These will be briefly treated in order:

(1) The Gas.

The first limitation to the upward extension of the gas scale is a direct result of the choice of a gas. Hydrogen was chosen because it approximated more closely to a perfect gas in its behavior than any other, but the experimental development of the subject has since demonstrated that no vessel can be depended upon to hold it without loss above 300°, so that nitrogen has come to be very generally substituted for hydrogen at the higher temperatures.

With reference to the situation created by this substitution, a long series of comparative measurements by Jaquerod and Perrot,[3] using air, nitrogen, oxygen, carbon monoxide, and carbon dioxide, shows no measurable differences in the behavior of these gases for thermometric purposes up to the melting temperature of pure gold (1062°), but some of these certainly could not be carried far beyond this temperature without danger of serious error through dissociation.

Nitrogen has been used, both in the Reichsanstalt and in the Geophysical Laboratory, as high as 1600° without any appearance of irregularity in its expansion or evidence of dissociation. The extension of the hydrogen scale by the use of nitrogen above 300°therefore encounters no serious difficulty up to the present limit of measurement (1600°) except in so far as it may prove necessary to make a small correction (of the order of magnitude of 1° at 1000°) for reference to the true thermodynamic scale if it is desirable to express the results of measurement in terms of it.

(2) The Bulb.

The bulb is perhaps the most important single element in a constant-volume gas thermometer. The progress of gas thermometry during nearly 100 years has been closely associated with and dependent upon improvements in the bulb. The first bulbs were made of metal (Prinsep used a gold bulb in 1827), and there is little question to-day but that their abandonment for porcelain in 1857 (Deville and Troost) constituted a step backward which was not retrieved for 40 years. The bulbs in use at the Reichsanstalt up to 1897 were still of porcelain, as were those used by Barus throughout his epoch-making work.[4]

Porcelain, glazed or unglazed, violates both essential conditions for a good gas thermometer bulb at high temperatures: (1) It cannot hold the expanding gas without absorbing or losing any of it; and (2) it is not absolutely uniform in its own expansion and contraction. Bulbs of platinum containing 10 to 20 per cent of iridium for additional stiffness were used at the Reichsanstalt in 1900 for temperatures as high as 1200°, and one of pure iridium was successfully carried to 1600° in 1907. These bulbs are still in use.

The Geophysical Laboratory began its work with a 10 per cent platin-iridium alloy, but abandoned it for platinum con-

[1] In a recent paper, "Some New Measurements with the Gas Thermometer," *Amer. Jour. Sci.* (4) 26, 405-463, 1908, the authors gave it as their opinion that the determination of the expansion coefficient of the thermometer bulb used by Chappuis, which is, of course, an important factor in the experimental problem, would not warrant an assumption of accuracy greater than 0.005°. To this Chappuis replied in a personal letter (1909) that, considering all the factors of the problem and subsequent experience, he still thought 0.002° a fairer estimate of the probable error of the scale in the region between 0 and 100°.

[2] An incident may serve to illustrate the fact that the gas thermometer is but a name to a great many otherwise well-informed scientific men. Soon after the appearance of one of the writer's earlier papers upon the subject, a well-known engineer wrote to inquire the cost of a dozen gas thermometers, to which I was under the necessity of replying that I knew of but one in this country, and this one had cost us upwards of four thousand dollars to date and might cost even more before we had finished with it.

[4] Carl Barus, "On the Thermoelectric Measurement of High Temperatures," *Bull.* 54 (1889), U. S. Geol. Survey.

taining 20 per cent of rhodium, for reasons which will appear in connection with the use of thermoelements below. All these metal bulbs can be used with nitrogen up to 1600° without appreciable error in the return to 0° after heating, provided only that proper precautions are taken against mechanical strain and consequent volume change at the higher temperatures where the metal is soft.

Porcelain bulbs when unglazed are not gas tight; glazed within, they can be used up to 1100° without serious error, but the glaze becomes soft above this temperature and reacts to some extent with the gas in the bulb which then never returns to its initial pressure at 0°. Porcelain bulbs with outside glaze only were employed by Barus up to 1400° with fair success, but it proved impossible to permanently saturate the bulb wall with the gas, so that it would return to the same zero after heating.

Pure silica bulbs which have recently been introduced by Jaquerod and Perrot (loc. cit., 1905) have an advantage over the metals through their low expansion coefficient, but cannot be used above 1100° without permanent volume changes.

In view of the other improvements which have been made in recent years (notably, the introduction of electric furnaces), it is difficult to estimate the proportion of error in the earlier measurements for which the porcelain bulbs were responsible. Barus' value for the melting point of gold (1888—porcelain bulbs) was 1092°, Violle's (1889—porcelain bulbs), 1035°; Holborn and Wien's (Reichsanstalt, 1895—also porcelain bulbs), 1027°; Holborn and Day's (Reichsanstalt, 1900—platin-iridium bulb), 1063.5°; Day and Sosman's (Geophysical Laboratory, 1910—platin-rhodium bulb), 1062.4°.

(3) The Furnace.

Improvements in the furnace have twice contributed materially to the advancement of gas thermometry: (1) Through the substitution of electricity for gas as a source of heat (Reichsanstalt, 1899), which greatly reduced the uncertainty in temperature distribution over the bulb surface and eliminated the possibility of furnace gases passing into the thermometer itself through the bulb wall; and (2) when the bulb and heating coils were enclosed in an air-tight bomb (Geophysical Laboratory, 1908) under conditions such that the air pressure outside of the bulb could be kept under control and always maintained equal to the pressure of the expanding gas within.

This second improvement made it possible to relieve the bulb from mechanical strain at high temperatures where the metal is soft and susceptible to volume changes, and considerably increased the effective range of the instrument in the high temperature region. It also became possible to use different initial pressures within the thermometer bulb in order to evaluate the pressure coefficient of the expanding gas and to vary the sensitiveness of the instrument.

Before this improvement was made it was necessary to select an initial gas pressure such that the final pressure at the highest temperature to which it was expected to attain would be approximately equal to the atmospheric pressure without, in order that the difference in pressure within and without the bulb should be a minimum when its power to withstand such a difference was smallest. The practical effect of the earlier arrangement was to crowd the entire range of the instrument into ½ m of the manometer scale, giving about ¼ mm per degree. With the air-tight furnace bomb we were able to increase this sensitiveness to a full millimeter for each degree.

To the introduction of electric heating we owe the extension of the range of the gas thermometer from 1150° to 1500°; to the control of the gas pressure about the bulb, a considerable (perhaps five-fold) increase in its accuracy in this region.

With electric heating, the furnace temperature is always under control and readily measurable, but in pursuing high standards of accuracy we must distinguish between a constant furnace temperature of irregular distribution and a variable temperature. The substitution of electricity for gas has given us a constant temperature, but it is not always easy to provide that it shall also be perfectly uniform.

Various baths are available up to perhaps 700° for the purpose of equalizing the temperature about the bulb by interposing between it and the heating coil a liquid layer which can be stirred, but higher temperatures have had to depend upon direct exposure to the radiation from the coil. In the Reichsanstalt instrument, temperature differences of from 10° to 30° were observed between the middle and ends of the bulb in the region 1500°-1600°; in that of the Geophysical Laboratory, the maximum differences were diminished to 2° in the same region.

For greater uniformity than this some form of liquid bath will require to be devised for use at these temperatures also. Such a search might prove worth while, for this uncertainty (in the distribution of temperature about the bulb) appears to be the largest remaining in gas thermometry up to 1550°.

(4) The Manometer.

The manometer contains few factors which affect the ultimate temperature readings materially. The arrangement commonly adopted, both in Europe and in this country, is the open U-tube type in which the difference in the mercury level between the two arms of the U-tube represents the difference between the gas pressure within the bulb and the prevailing atmospheric pressure outside, the latter being read on a separate barometer. The minor corrections for temperature of the mercury, gravity, etc., then require to be applied as usual in such cases.

The only real difficulty encountered here has been much reduced in recent years and is no longer dangerous, even at the highest temperatures. The temperature of the capillary connection between the bulb and manometer varies all the way from the extreme temperature of the bulb to that of the room and with it the temperature of so much of the gas as it contains. The error from this cause is reduced to an insignificant magnitude by making this connecting volume so small when compared with that of the bulb that its average temperature need only be known within about 10 per cent.

Some laboratory experience is necessary to make this reduction of volume judiciously, for the viscosity of gases increases rapidly with the temperature, so that it is not practicable to restrict below 0.8 mm the diameter of those portions of the capillary which are heated. A smaller diameter here would have the effect of producing a very slow readjustment of pressure in the various parts of the apparatus with every change in the temperature, and the observer would be without adequate assurance that equilibrium had been reached at the time when his reading was made.

The uncertainty which attaches to this connecting volume, together with the changes in the zero point due to the irregular behavior of porcelain bulbs, were among the most formidable of the classic errors of gas thermometry. Both are now practically eliminated.

(5) The Auxiliary Thermoelement.

The fact that the gas thermometer bulb cannot be safely immersed in different substances for the determination of their thermal constant carries with it a considerable amount of incidental but practically unavoidable inconvenience. The usual plan has been (and still is) to place thermoelements in the furnace with the bulb and to determine their electromotive force for a measured temperature. A few observations of this kind suffice to establish an empirical curve for the electromotive force of the thermoelement in terms of the gas thermometer temperatures, after which the thermoelement is available for determinations of temperature under a great variety of conditions.

This procedure is considerably facilitated by the fact that the empirical curve corresponds closely to a simple parabola and three or four comparisons with the gas thermometer usually suffice to establish a parabolic curve which may be interpolated with little danger of an error greater than the errors of the

gas scale itself over long ranges of temperature. Its extrapolation has not turned out so fortunately.

Before the publication of the recent measurements in the Geophysical Laboratory, the region of accurate gas thermometry ended with the temperature 1150°. The common practice for some years has therefore been to measure temperatures beyond that point by extrapolating the parabolic curve out to the desired temperature—often as high as the melting point of platinum (1755°). Extended extrapolation is always a matter of grave uncertainty, but no other convenient method was available, and after all, observations of this kind with the thermoelement could be translated in terms of an observed scale whenever one should be provided. It happens in this particular case that the extrapolation (from 1150° to 1755°) comes out just 50° low at the platinum melting point.

Now that the gas thermometer is able to make direct measurements of temperature up to 1550°, it is merely necessary to include several thermoelements in the furnace with it, to evaluate their temperature curves by direct comparison, and afterward to determine with them a series of standard fixed temperatures like the melting points of metals, minerals, or salts, which are available for general use.

This procedure has been followed in the recent investigation with the results which are tabulated below. The pure metals are readily obtainable and the minerals easily made up, so that anyone may now calibrate his thermoelement by noting its electromotive force at the (known) melting temperature of three or four of these substances, preferably choosing such as will include the region in which he expects to use the thermoelement.

Such a calibration requires to be checked from time to time by repeating one or more of the melting point observations, particularly if the element is exposed to contamination for vapors of other metals. This contamination is particularly disastrous if a thermoelement is exposed to the vapor of iridium, which explains the remark made above, that in our experience a bulb made from an alloy of platinum and rhodium is to be preferred to the iridium alloy in use at the Reinsanstalt.

The standard melting points in the table below are taken from observations by Day and Sosman[5] and include, for comparison, the standard melting points published by the Reichsanstalt in 1900 and now in general use:

Substance	Point	Atmosphere	Crucible	Temperature	The Reichsanstalt Scale
Zinc	Melting and freezing	Air	Graphite	418.2° ±0.3	419.0°
Antimony	Do.	Carbon monoxide	Do.	629.2 ±0.5	630.6
Silver	Do.	Do.	Do.	960.0 ±0.7	961.5
Gold	Do.	Do.	Do.	1062.4 ±0.8	1064.0
Copper	Do.	Do.	Do.	1082.6 ±0.8	1084.1
Diopside (pure)	Melting	Air	Platinum	1391.2 ±1.5	
Nickel	Melting and freezing	Hydrogen and Nitrogen	Magnesia and Magnesium Aluminate	1452.3 ±2.0	
Cobalt	Do.	Do.	Magnesia	1489.8 ±2.0	
Palladium	Do.	Air	Pure Magnesia	1549.2 ±2.0	1575.2
Anorthite (pure)	Melting	Do.	Platinum	1549.5 ±2.0	

In addition, the following temperatures were incidentally obtained:

Cadmium	Melting and freezing	Air	Graphite	320.0 ±0.3	321.7
Aluminum	Freezing	Carbon monoxide	Do.	658.0 ±0.6	657.
Platinum	Melting	Air		1755.	

A new estimate of the melting point of platinum, which has not yet been directly determined with the gas thermometer, is included in the above list. It was obtained in this way: There is a remarkably close agreement between independent determinations of the *temperature interval* between the melting points of palladium and platinum:

Nernst and von Wartenberg[6] ..... 204°
Holborn and Valentiner (at the Reichsanstalt[7]) ..... 207°
Waidner and Burgess (at the Bureau of Standards)[8] .. 207°

If we, therefore, simply add 206° to the palladium melting temperature (1549°), we obtain 1755° as the melting point of pure platinum, with an absolute error of perhaps no more than ± 5°.

By way of conclusion, the following estimate is offered of the accuracy of existing standards of temperature within certain temperature intervals:

0° — 100° ± 0.002°
100° — 300° ± 0.05°
300° — 1100° ± 0.8°
1100° — 1550° ± 2°
1550° — 1750° ± 5°

Sintering of Fine Ore and a Sintering Machine.*

By Alfales B. Young.

Among the metallurgical developments of the last decade one of the most important has been the sintering treatment of fine ore, which beginning as a step in the reduction of lead, with its chief object the securing of a dead roast, has come to be a prominent factor in copper smelting, where its object other than that of obtaining the roast, is also the preparation of the product in a sintered or agglomerated form suitable for blast-furnace work. The first to bring forth the idea of a blast roast were Huntington and Heberlein, whose names have been so linked with sintering in general that a great deal of it is known under the heading of the "Huntington-Heberlein process," although it does not, strictly speaking, belong to their invention.

In a general way, the process of sintering may be classified in two divisions, viz., those requiring a preliminary roast and those in which the raw ore is sintered directly. The former belong to the Huntington-Heberlein process, and in the latter are the Carmichael-Bradford, the Savelsberg, and the Bormette processes.

The above is only a partial list, but I think it contains the more important methods.

The characteristic feature of the Huntington-Heberlein process is the addition of limestone to a partially roasted galena ore. The fine galena concentrates are mixed with limestone and slag-making material, and this is given a preliminary roast. The first roast eliminates sulphur to the extent of 6 per cent to 8 per cent. The Godfrey rotating-hearth roaster was formerly preferred for this part of the operation, but any of the modern types of roasting furnaces will serve the purpose.

The Huntington-Heberlein sintering pot or converter is shaped like an inverted dome having a diameter of 8 ft. or 9 ft. About 1 ft. from the bottom a grate, convex upward, is fitted in the portion of the pot under the grate, having an opening or tuyeres for attaching an air pipe and thus constituting a windbox. Over the pot is a hood, attached to a flue or stack, which may be raised out of the way. Usually there is a row of pots over which runs a traveling crane for charging and dumping them.

Prior to charging, a thin layer of coal ashes is spread over the grate. On this is dumped a layer of hot calcines from the roaster, and on this, in turn, the regular charges of calcines, moistened with water. The time of sintering varies from 8 to 14 hours, and a product with about 2 per cent sulphur is ob-

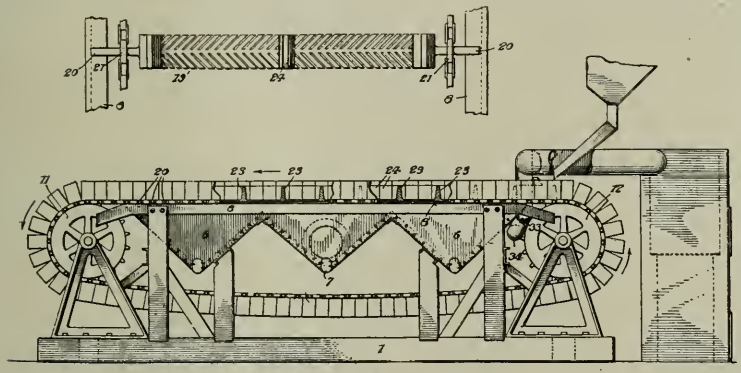
tained. The addition of limestone seems to aid the roasting and at the same time prevents a premature fritting before the roast takes place. This is probably accomplished both by a mechanical action of the particles and by absorption of heat in the breaking down of the calcium carbonate molecule into lime and carbon dioxide. The sintering material is dumped from the pot by the crane, where it is sprayed with water and broken up by sledging.

The Carmichael-Bradford process employs dehydrated gypsum instead of limestone. The process is carried on in the same form of pot as the Huntington-Heberlein. The charge at Broken Hill, where this method has met with success, consists, roughly, of one part dehydrated gypsum, three parts of slimes and one part of sand concentrates. The sulphur content of the charge is about 16 per cent and of the product about three. The material for the charge, mixed and moistened in a pug mill, is broken into nut-sized lumps while still wet and spread out and allowed to dry in the sun. The charging of these small lumps enables an extremely free passage of air through the mass, giving a good sinter and lessening the time of the operation.

The Savelsberg process is like the Huntington-Heberlein in that the flux used is calcium carbonate, but differs in the fact that a preliminary roasting is unnecessary. By the addition of sufficient limestone the heat from the oxidation of the contents



APPARATUS FOR SINTERING FINE ORES.

of the charge is absorbed by the breaking up of the carbonate. The sintering pot is of the same general shape as that previously described. However, instead of being manipulated by a traveling crane it is mounted upon a track, much after the fashion of the ordinary slag pot.

The Bormette method of lead and copper smelting consists of the incorporation of the fines in a predetermined amount of liquid slag, accompanied by rapid stirring in the pot. A porous, spongy mass is evolved with about 50 per cent desulphurization. These sintering processes, briefly described, have been gradually taken over into copper work, where mine fines, matte and flue dust have been agglomerated with varying degrees of success. The addition of lime and other kindred substances has practically been eliminated, as the prevention of premature sintering is not required. It has been my experience that the addition of quartz or lime, as the case may be, in such quantities as to give a monosilicate in the slag part of the sintered mixture, gives the best results both in time of sintering and in percentage of charge sintered. With a copper ore running SiO_2 14 per cent, S 27 per cent, Fe 45 per cent, Al_2O_3 4 per cent and lime and magnesia 4 per cent, using a size ½ in. or smaller, I have had success in mixing flue dust to the extent of almost one-third by volume, securing in a Huntington-Heberlein pot a sinter of 85 per cent to 90 per cent of the total charge to 10 per cent to 12 per cent sulphur in seven or eight hours.

The unsintered portion is almost invariably a layer of from 4 in. to 8 in. at the top of the pot. As might be expected, the presence of fairly coarse pieces in the charge is an aid to the action.

The future of sintering as an economic method of roasting copper fines depends chiefly upon the cost of operation plus the cost of smelting in the blast furnace as compared with the cost of roasting in the ordinary way plus the cost of smelting in a reverberatory; and, secondly, the cost of ordinary smelting plus briquetting, as compared with the cost of sintering.

In lead work the Huntington-Heberlein process has proven itself far cheaper than the old lead reverberatory. The best we may say, however, in regard to sintering intermittently in pots is that it is crude. In the first place it is a theoretical waste of capacity for the sintered layers to be dormant in the bottom of a pot waiting for those above to be treated in the operation; secondly, it is a waste of power, having to drive air at a necessarily higher pressure through the layers below in order to reach those above to act upon them; and, thirdly, the handling of the large lumps of sinter is, at best, a clumsy and expensive operation.

The solution of the problem lies in the development of a continuous sintering machine, taking and discharging the sintered material in thin layers. To the solution of the latter part of the problem Messrs. A. S. Dwight and R. L. Lloyd have contributed the down-draft system, in which the air is sucked or blown toward the grate, thus maintaining a lack of movement among the particles and preventing the layers away from the ignition surface from remaining unsintered. This, of course, has its disadvantage in the corrosive, moist, sulphurous gases having to pass through the pipe connection and the suction fan.

To the solution of the former part of the problem I have applied merely the endless-belt idea and erected partitions on the bars of the traveling grate, dividing it into compartments, thus dividing the sinter in blocks of suitable size requiring no further breaking or crushing.

This sintering machine consists essentially of a grate in the form of an endless traveling belt which carries a bed of fines and passes for nearly its entire length over a suction or wind box, by which air is drawn through the mass. Means are provided at one end for distributing the layer of fine material over the surface of the grate and for its ignition, and at the other end the sintered product is discharged into a convenient receptacle.

Referring to the drawings, the grate consists of numerous cast-iron segments (19) carried upon the links of the chains (21) which move upon two pairs of sprocket wheels (11 and 12). The segments of the grate are provided with projecting arms (20) which rest upon rails (8) in order to prevent sagging.

Directly beneath the grate is a wind or suction box (6), to which a suction pipe is attached leading to the suction fan furnishing the draught. The sprockets are mounted upon bearings and the rails and the suction box, etc., upon supports, all of which rest upon the bed frame (1).

On the right hand of the drawing are shown the ignition apparatus and the distributor. The former consists of a small furnace or stove of the reverberatory type, from which the flames are led by a pair of flues around the distributor and into the igniter, which is merely a long sheet-metal box extending

in length the width of the grate and probably 3 in. to 6 in. wide.

This box is, of course, open at the bottom and the flame passes from it directly through the ore. Upon this igniter is mounted the plow (40). Fines from the distributor falling upon the grate are spread out evenly as they travel under this plow. Thus the igniter fits closely to the surface of the ore.

Right under the igniter, and beneath the grate, is a special suction box (33). This is connected to a special suction pipe (34), thereby giving at the point of ignition a very much stronger draught than that of the large section box (6). This insures the first-class priming—the chief essential to good sintering.

Chain.—This would be one of the standard roller chains made by transmission machinery manufacturers. The rollers would carry the chain upon the rail (8) and upon a rail on the under side (not shown) where the grate travels back.

Grate.—This grate is divided into compartments by the centrally located ribs (24) and medial ribs (23) upon every third or fourth segment. These ribs are as high as the top of the layer of ore; thus it is sintered in blocks and requires no subsequent breaking of any kind. Any form of perforation may be used for grate holes, although I have shown a fishbone arrangement, the elongated holes extending across the halves of two segments, thereby breaking in the middle when going around the sprocket and tending to dislodge any accretion which may have formed. These grate segments are so designed that replacing them is a very easy matter.

Suction or Wind Box.—(6) The peculiar shape of the bottom is for the purpose of facilitating the removal, through the handholes of any material which may have fallen through the grate.

Frame.—Although this is shown in the drawing as being of wood, it may be made of structural steel.

Operation.—Fine ore, flue dust, etc., are fed from the bin and feed hopper (diagrammatically indicated) to the machine through the distributor. The layer is spread evenly by means of the plow and passes under the igniter, where a strong flame is sucked through it. It then goes over the suction box, where air is drawn through the mass and roasting and sintering takes place. This continues until the end of the machine is reached, where the grate, turning around the sprocket, breaks away from the sinter, which discharges at this point. Here a spray of water will be constantly playing to cool the blocks.

The speed of the machine will be from 6 in. to 1 ft. per minute; the draught a vacuum of about 5 in. or more of water (3 oz. per square inch). The over-all length of a machine, of 30 tons to 40 tons daily capacity, is 18 ft. and the width of the grate 3 ft.

Features.—(1) The machine is very compact for the amount of effective grate area, occupying small floor space and requiring little head room.

(2) The separate suction for the igniter insures a much stronger draught at the point of ignition, and consequently the top layer is thoroughly sintered.

(3) By use of the compartment grate all hand breaking of the sinter is eliminated.

(4) The grate going around the sprocket and thus changing curvature at the point of discharge, breaks away from the sinter and obviates the barring and wedging necessary when a grate of constant curvature is used.

The machine can be used with the regular up-draught by making the suction box (6) a wind box; the suction fan a blower, reversing the position of the igniter, placing it under the grate end and priming through it. In this case a hood should cover the grate.

The cost of sintering with this machine would be far lower than with pots. The mechanical arrangement of a plant operating with these can be so adjusted as to make labor a minimum. The ore and flue dust, or whatever mixture is used, can be thoroughly mixed in a concrete mixer, or a similar appliance, and taken directly to the feed hopper for the machine, where the firing of the igniters and the regulating of the charges for a battery of several machines can be attended to by one man. The dumping is automatic and the sinter could drop directly into small bins just above the charging floor level of the blast furnaces—that is, should the topography of a smelter site allow such an arrangement. At any rate, the labor required would be a minimum. With the exception of the Bormette process, the use of which is not extensive, any of the ordinary sintering methods can employ this machine, and with its reduced cost of operation, I think it will go quite a way in making sintering an economic success.

The Attainment of Highest Purity Iron on a Commercial Basis.

By James A. Aupperle.

The United States Patent Office recently granted to R. B. Carnahan, Jr., two patents,* No. 940,874 and 940,875, covering the process and product for the manufacture of iron of exceptional purity. This iron is known in the trade as American ingot iron and is manufactured by the American Rolling Mill Company of Middletown, Ohio. It possesses properties so radically different from steel, that a description of the process and product will be of interest.

The process of manufacturing American ingot iron consists of charging a high-powered basic open-hearth furnace with iron and high-grade scrap, employing therewith agents for the elimination of the carbon, manganese, silicon, sulphur, and phosphorus, refining the charge in a molten condition at such a high and increasing temperature, and for such a prolonged period, that analysis of bath test shows that the sulphur, phosphorus, carbon, manganese, and silicon, are not over 0.14 when taken in the aggregate, pouring the hot purified iron into moulds, and while in a molten condition, deoxidizing and degasifying to such an extent that the product will not contain over 0.05 oxygen as determined by the method of Ledebur, but will contain at least 99.80% iron.

In practice it is possible to eliminate the silicon, sulphur, phosphorus, carbon, and manganese to 0.03 when taken in the aggregate. The manufacture of American ingot iron is a process of elimination from start to finish, one of the eliminating agents being oxygen.

FIG. 1.—COMPARATIVE TRANSVERSE SECTIONS OF INGOTS.

The process is based on the assumption that iron will not dissolve more than 0.30 oxygen. It is thus a very flexible process, as a large excess of iron ore or mill scale can be added to the bath for the purpose of eliminating the impuri-

*See pages 62 and 98 of the February issue of this journal.

ties, and at the same time the bath at the end of melt will not contain more than 0.30 oxygen, which is then partly deoxidized in the furnace with pig iron, or ferro-silicon.

The deoxidation and degasification are completed in the ladle with aluminium, so that the finished iron will contain less than 0.05 per cent. oxygen and more often the oxygen content will be nearer 0.01 per cent.

Fig. 1 shows a transverse section sawed from the middle of ingots on which no rolling or hammering was done. It shows how completely American ingot iron (at the right) is degasified and also shows the large number of blow holes in the steel (at the left). These ingots were of the following analysis:

	American Ingot Iron.	Steel.
Carbon	.010	.10
Manganese	.003	.35
Silicon	.002	.012
Sulphur	.015	.031
Phosphorus	.001	.065
Oxygen	.012	.034
Specific Gravity	7.95	7.72

It will be seen that the specific gravity is considerably higher in American ingot iron than steel, and often exceeds 8.00 in the rolled sections.

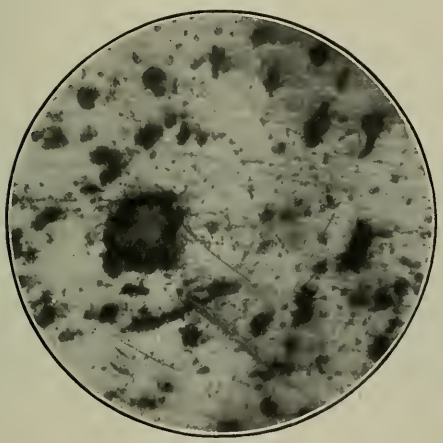


FIG. 2.—TRANSVERSE SECTION. WROUGHT IRON. 56 DIA. SLAG SPOTS. NOT ETCHED.

The importance of low oxygen content of American ingot iron was early recognized, as it was found that besides making the iron red short, it would not galvanize economically if the oxygen exceeded 0.05. The excess of oxygen also caused rapid corrosion. A sample containing above 0.05 oxygen will dissolve more rapidly in acid than material containing below 0.03 oxygen, which is undoubtedly due to the electro-negative character of oxygen, it being more electro-negative than any other element, with the possible exception of fluorine.

The remarkable resistance of American ingot iron to corrosion is shown by the fact that in a 25 per cent. solution of sulphuric acid at 70° C. some grades of 16-gauge Bessemer sheet steel will dissolve in 30 minutes, while under the same conditions, American ingot iron will lose 1 3 of 1 per cent, or in the ratio of 1 to 300.

However, in open-hearth steel of low oxygen contents, the loss is much less than in Bessemer steel, but the American ingot iron is at least twenty times as resistant to sulphuric acid attack as the best open-hearth steel.

Another instance is shown by a neutral copper-sulphate test, where the American ingot iron is several times better than open-hearth steel. This fact is interesting, as it makes the metal suitable for use where there is water containing copper in solution.

In fused caustic soda it outlasts steel about two to one. American ingot iron enamels far better and can be more easily drawn than steel, and also alloys better with cast iron, so that molten cast iron can be poured around it and a perfect union takes place.

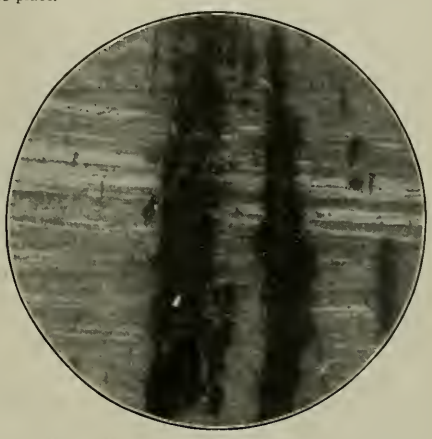

FIG. 3.—LONGITUDINAL SECTION. WROUGHT IRON. 56 DIA. SLAG LINES. NOT ETCHED.

The following table shows the physical properties of American ingot iron to be superior in every respect to wrought iron.

Material	Elastic Limit	Ultimate Stress	Per Cent. Elongation 8 in.	Red. of Area
American Ingot Iron (unannealed)	32290	55550	22.4	54.0
Wrought Iron	30400	49050	16.0	22.4

From the fact that American ingot iron is made in an open-hearth furnace, there is a tendency to call the material steel, but

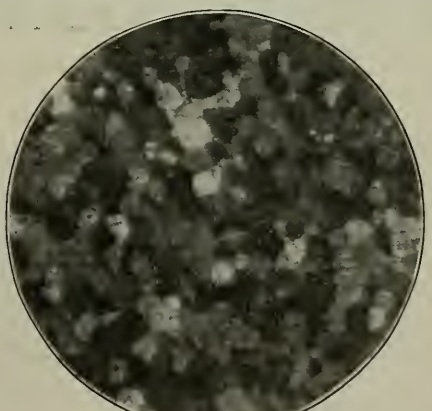

FIG. 4.—AMERICAN INGOT IRON. 56 DIA. DEEPLY ETCHED. GRAINS OF FERRITE.

steel being a compound and American ingot iron practically an element, there is no good reason for calling it steel, and when examined under the microscope, the structure seen is ferrite, which according to the present nomenclature is nearly pure iron. About the same amount of pearlite is present as in the

best Swedish iron (traces only). The micro-structure of American ingot iron and Swedish iron is identical as to the ferrite constituent, the only difference being a few scattered slag lines in the longitudinal and slag dots in the transverse sections of Swedish iron.

In a microscopical examination of a longitudinal section of the common grade of wrought iron (Fig. 3) the large slag lines show a marked difference between it and American ingot iron, which contains no slag.

Fig. 5 shows the effect of positive and negative elements in contact with American ingot iron.* Dish No. 1 shows the effect of carbon in contact with American ingot iron, the carbon being electro-negative, the hydroxyl ions cluster about it and are indicated by the phenolphthaline producing a red color. The positive iron dissolves and is indicated by the blue color produced with potassium ferri-cyanide. American ingot iron contains but traces of carbon, consequently there is less electrolytic action than in steel, which often contains a considerable amount of carbon.

Dish No. 2 shows the effect of oxide of iron in which is a piece of wire, one-half containing oxide of iron, the other half free from oxide, and thus shows the electro negative character of the oxide of iron, the narrow half of the wire being the oxidized side, the wider half showing where the iron has gone into solution, forming Turnbull's blue, while the side containing the oxide of iron became red from the presence of hydroxyl ions.

American ingot iron being exceptionally low in oxide of iron, there will be less electrolytic action than in steel containing considerable oxide of iron.

In Dish No. 3 the electro-positive nature of zinc is plainly indicated, in which a piece of zinc is placed in contact with a strip of American ingot iron, in this case the hydroxyle ions cluster around the iron producing a red color, the zinc in this instance dissolving as zinc hydroxyle and thus protects the electro-negative iron.

This would indicate that should the spelter become broken on American ingot iron there would be very little iron corroded, until the zinc has all disappeared and thus indicates the excellent protection that zinc imparts to iron.

Fig. 6 shows how much better American ingot iron alloys with zinc than steel and also the better protection afforded in resisting the corrosive action of sal ammoniac flux. Two collars, one ingot iron, the other steel, each $4\frac{1}{4}$ in. diameter were put on the necks of the exit rolls of a galvanizing machine, one-half of the roll was immersed in molten spelter, the other half surrounded by sal ammoniac flux. The steel collar corroded five times as fast as the collar made from American ingot iron.

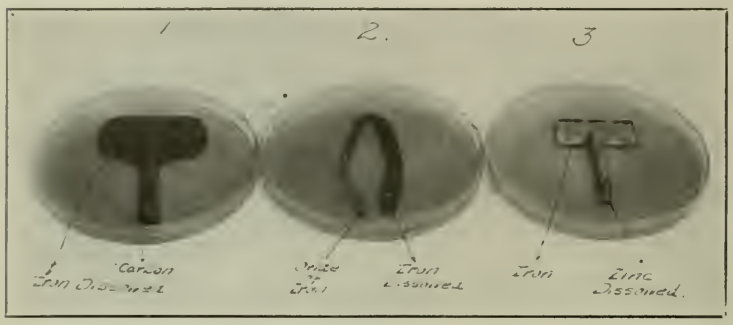

FIG. 5.—ELECTROLYTIC CORROSION TESTS.

FIG. 6.—STEEL COLLAR AND INGOT IRON COLLAR.

Professor Charles F. Burgess of the University of Wisconsin, has the following to say about American ingot iron:

"From time to time we have made microscopic examinations of American ingot iron and have found its structure to indicate high purity, homogeneity, and absence of slag. And from the microscopic appearance we have every reason to believe this iron to be equal to the best Swedish iron in its physical properties and to have the advantage over Swedish iron due to the absence of imperfections caused by slag.

"We have used a large amount of this material for the

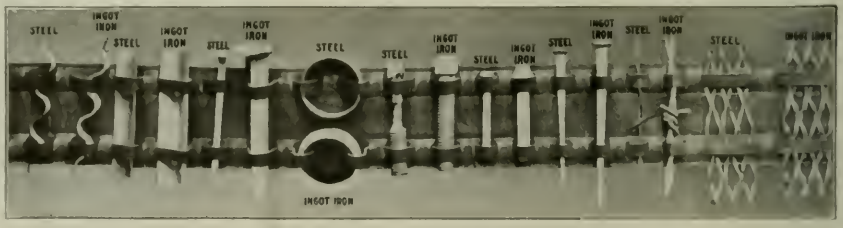

FIG. 7.—INGOT IRON AND STEEL CORROSION TESTS.

*For the electrolytic theory of corrosion and methods of making the anode and cathode spots visible by different colors, see especially the papers of Cushman and Walker, for instance, Vol. V of this journal, pages 264 and 305 (1905).

anode in our electrolytic refining tanks and the manner in which it corrodes shows that it is more dense and uniform than most of the other soft irons we have tried. It is comparatively free from fibers which are so pronounced in some grades of soft iron, which we have employed. In our magnetic tests also, the ingot iron seems to be strictly comparable to high-grade wrought iron.

"As regards corrosion, our experience has been that on ac, count of the absence of impurities, and the uniformity of its structure, there is less local electrolytic action than in most other grades of iron. The result of this is that it dissolves less rapidly than will most other forms of iron."

Prof. J. W. Langley, of Ann Arbor, Mich., refers to American ingot iron as follows:

"American ingot iron is extraordinarily tough and ductile, ranging above wrought iron, and closely approximating the best grade of mild steel of .10 carbon.

"Its combination of great ductility with a fair degree of tenacity is remarkable, and when considered in connection with the resistance to corrosion, makes a distinctly new metal of it. In resistance to acids such as diluted sulphuric and hydrochloric, it resists on an average about twenty times the corrosion of open-hearth steel."

MIDDLETOWN, OHIO.

The Chemist in the Brass Foundry.*

BY W. M. CORSE.

The statement has recently been made that the twentieth century is going to be the era of the chemical engineer, as the nineteenth was of the mechanical engineer. One has but to look about him to see evidences of this development to realize the truth of this statement. More and more of our manufacturers are coming to see that the underlying principles of their processes are chemical and that a knowledge of these principles is essential to the proper conduct of their business if it is to be run at a profit. The brass manufacturer has begun to see this condition, and the number of testing laboratories that have been installed in connection with this industry are proof of this fact.

I have had the good fortune to install four chemical laboratories, three of which have been in connection with brass foundries. A short history of their development may be of interest. The first came into being because of the trouble the manufacturer had with metal melted in oil furnaces. The furnaces did not use a crucible, and the flame came into direct contact with the metal. Oxidation of the metal was greater than in the old-style crucible coke furnace, and the composition of the mixture was varied to such an extent that very bad results were obtained from the castings when they were subjected to hydraulic pressure.

My first work was to ascertain the amount of oxidation and volatilization in order to maintain the composition of the resulting alloy uniform. Numerous tests were made and it was found that 35 per cent more zinc was lost than was allowed for. It was also found that all the remelt was put into one general pile and as this amounted to 50 per cent of the melt, the indiscriminate use of this remelt changed the formula very materially. One thing led to another, until finally all formulas for metal were made up in the laboratory and the resulting melts were analyzed regularly to see if these formulas gave the desired result.

This all may seem very simple, and undoubtedly is, but the fact is that the majority of brass founders are in ignorance of just these principles of their daily operation. The last seven years have witnessed remarkable strides along such lines as described, so that some foundries now know considerably more than they did before the chemist was employed.

* Presented at the March meeting of the Chicago section of The American Chemical Society.

Many times I have been asked the question, "Of what use is a chemist in a brass foundry?" This question was asked by men actually operating foundries. To-day the number of analyses made is probably 500 times as many as five years ago. Although the manufacturer may not have come to the point of using the chemist, he is generally willing to concede his value.

From testing the furnace products for formula, I worked to examine the raw materials for purity. These include copper, tin, lead, zinc, ingot brass, scrap brass, and sometimes antimony. Aluminium also comes in prominently for some kinds of work and has to be tested. The majority of aluminium casting makers buy their alloys ready made as it were, so that less work is done on their component parts than on finished alloys.

The cost of an alloy is, of course, determined by the cost of its component parts, and when these vary quite widely in price, a variation in composition sometimes means the difference between profit and loss. For instance, copper costs now about 14 cents per pound and zinc and lead average 5 cents per pound. An alloy figured for 70 per cent copper, but actually carrying 72 per cent will cost 18 cents a hundred pounds more than it should cost. On a weekly melt of 100,000 lb. this means $180 a week, or $9,360 a year.

This is by no means an unusual instance, and goes to show what a very small saving per pound may mean. It also shows how the exact control of a formula may save money for the manufacturer. It is safe to assert that over a thousand pairs of metals have never been alloyed, and many times this number of combinations of three or more metals have never even been thought of. The surface of this enormous field has scarcely been scratched and offers as much promise for investigation as any that I know.

If any industry needs the attention of the technical man it is the foundry business. Rule-of-thumb methods predominate and opportunities for investigation lie at every hand.

In addition to the metallurgy, we have the various refractory materials and their connection with furnace design and upkeep. They comprise such things as fire brick, fire clay, fire sand and carborundum. The various molding sands come in for attention too. These should be tested for fineness, binding qualities, resistance to hot metal, porosity, etc. Core sands are tested for fineness and refractory qualities. Crucibles are an important item of expense and should be tested regularly to insure maintaining uniform quality.

Coke can be tested for ash and sulphur although a practical test for burning qualities is generally the most important. If oil is used for fuel, it also comes into the laboratory for test.

All brass foundries have copper-bearing refuse of various kinds, which cannot be worked up satisfactorily with the equipment generally available. In order to sell these for anything like their proper value, it is necessary to know either their metallic content or their copper content, which again makes work for the chemist.

As a general thing experimental work cannot be properly taken care of by the foreman. The nature of his duties prevents him from giving concentrated attention to any problem for any great length of time, inasmuch as continued interruptions render impossible the proper recording of his observations. The chemist is, therefore, the logical man to conduct this kind of work. It usually happens that the chemist is the only technical man around the foundry, so that it properly falls to his lot to record the results of all tests made, whether they are chemical, physical, or practical tests of material. He often can be of help in devising production records, loss reports and summaries of such things as pounds produced per man per day, fuel consumed per 100 lb. of metal melted and others too numerous to mention. He can do the planning for engineering work such as is commonly required in a foundry and can aid in the solving of such engineering problems as may arise.

I think I have made it sufficiently clear how a chemist can be used to advantage in any brass foundry large enough to warrant

the outlay for a laboratory. For smaller foundries the commercial testing laboratory is available and does very satisfactory work along some lines. Experience has shown me that many foundries would employ their own metallurgist, as the brass foundry chemist may properly be called, did they but realize the many uses to which his services could be put.

In my position as Secretary of the American Brass Founders' Association, I have had exceptional opportunities to watch the development of the brass foundry laboratory and I have observed that the manufacturers who are making the highest quality goods in a business-like manner are foremost in utilizing this department. Could the practical foundryman be made to realize that a technical man makes his own position more valuable and co-operation vastly increases his own usefulness, a great step forward would be taken in this ancient and intensely interesting industry.

Concentration of Sulphuric Acid.

In our February issue, page 97, we gave an account of the first part of an article by Dr. Gustave Lüttgen in the *Chemiker Zeitung* of January 11, on concentration of sulphuric acid.

The reason for this article is the fact that the hopes placed in the contact process for making sulphuric acid have not been fulfilled in the experience of the last few years, that the numerous difficulties have not been overcome, and that the process is very sensitive. Moreover, the chamber process has had marked improvements in design and operation, and as a result the necessity has arisen for presenting the latest improvements in apparatus for concentration of chamber acid.

The author discusses first the "dish system" (cascade), with its breakage, loss of acid and high fuel consumption; second, the tower system, with its difficulty of operation, expense of installation, high fuel cost and large production of weak acid;* and, third, the "pan system," perhaps better described as "entrainment system" Kessler).

Dr. Lüttgen's article goes on to say that the old Kessler apparatus is so well known that its detailed description is unnecessary. As there is, however, little general knowledge regarding the recent improvements in the Kessler apparatus, the most commanding points will be described.

In the old Kessler system the "saturex" consists of a rectangular chamber built of "volvic" lava having longitudinal channels of pumice stone. The hot gases passed into the "saturex" through channels open at the bottom and reaching downward to the surface of the acid contained in the saturex.

The principle itself was excellent, but the pumice stone was subject to disintegration and failed after a certain time. As a result the gases of combustion did not pass sufficiently through the acid before going to the recuperator, so that the output was decreased. Also these channels did not permit easy cleaning of the saturex because the pumice stone would not stand rough usage.

The Kessler works, owned by Mr. J. Teisset, have now remedied this by the following arrangements, patented by Teisset-Prat in 1909. Instead of the longitudinal pumice stone channels, transverse dividing curtains of volvic lava are now used. The saturex is thus divided into cells above, against which the acid waves caused by the counter flow of hot gases strike.

These changes have increased the output, and also made cleaning very easy, since dividing walls may be taken out for inspection and put back in place without any difficulty. There is practically no breakage and no accumulation of acid mud. The acid produced is always concentrated and perfectly clear.

In the old Kessler apparatus the hot gases were drawn through by one or two steam ejectors of special construction. The porcelain nozzle had to be adjusted very exactly to the steam pressure, and was a rather delicate piece of apparatus. Furthermore, steam pressure was subject to change, whereby the output was diminished. To overcome these disadvantages the steam jet has been replaced by a special apparatus at the end of the system. (Teisset-Prat patent, 1909.)

Some manufacturers tried to insert an exhauster of hard lead or soft lead between the apparatus and the filter. But in these cases it was found that the output decreased, and it was necessary several times in a month to take out the impellers for the sake of repairs necessitated by the attack of the hot acid vapors. There is no danger of this kind with the new apparatus, by which the air is forced from the outside into a pressure transformer inserted in the gas pipe coming from the coke boxes. In the pressure transformer the pressure is reduced, and this reduced pressure is communicated throughout the apparatus.

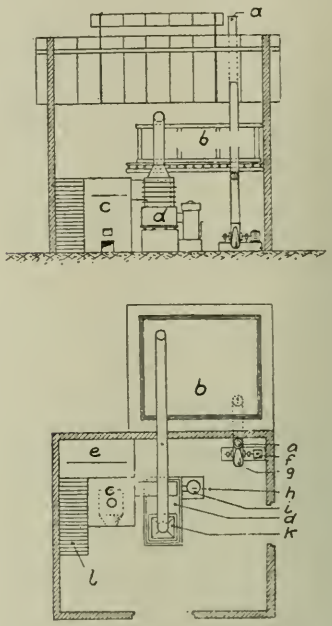

FIG. 1.—CONCENTRATION OF SULPHURIC ACID.

a, steam escape; *b*, condenser; *c*, gas producer; *d*, saturex; *e*, platform; *f*, electric motor; *g*, ventilator; *h*, acid exit; *i*, cooler; *k*, recuperator; *l*, stairway.

With this arrangement the acid vapors do not get into the pressure reducer, so that its life is practically unlimited. Further, while the steam escaping into the air was slightly acid with the old Kessler apparatus, it contains no acid whatever in the new apparatus. On account of these important improvements, the cost of concentration has been considerably reduced.

In the new Kessler apparatus from 80 to 100 kilograms of coke are required per ton of sulphuric acid of 92-93 per cent. The power required is 0.6 horsepower hour per ton. The quantity of weak acid is less than with the old Kessler apparatus, about 80 kilograms of 36° Beaume per ton.

Further, first chamber acid may be used, as the apparatus is very easily cleaned. With the old apparatus of 10-ton capacity two coke boxes were necessary, while one of them may be omitted with the new apparatus. The temperature of the gases when leaving the last plate is only 90°C.

The cost of installation in Germany of the improved Kessler apparatus with a capacity of 10 tons of sulphuric acid of 92-93 per cent is about $6,000, while the cost of repairs has been greatly reduced by the improvements.

* Concerning these two processes see our February issue, p. 97.

Steam is no longer required for the operation of the apparatus. Since electric power is now available everywhere, the new concentration may be placed wherever it is most convenient.

Finally, the new apparatus has also solved the important problem of concentrating chamber acid to acid 98 per cent at small cost. The ease of concentration is largely due to the improvements noted above, as well as the high thermal efficiency.

Radiation losses are reduced to a minimum by the compact construction of the apparatus. This results in a high thermal efficiency.

The coke consumption for concentration to 98 or 99 per cent is from 180 to 190 kilograms per ton; the energy required is 1.5 hp-hours per ton.

An apparatus which yields 10,000 kilograms of 93 per cent

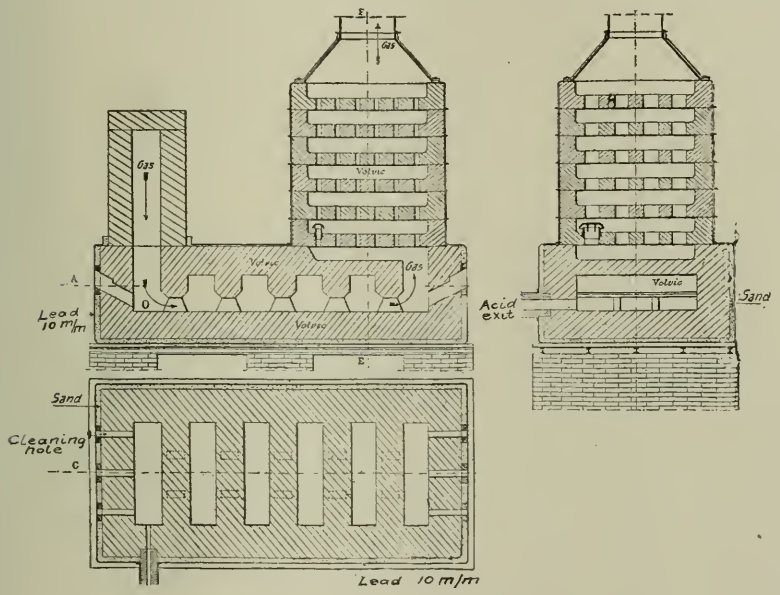

FIG. 2.—CONCENTRATION OF SULPHURIC ACID.

H_2SO_4 yields about 5000 kilograms of 98-99 per cent H_2SO_4. With this concentration the quantity of weak acid is less than 25 per cent.

The following table is a comparative summary of the results obtained with the various concentration apparatus described for a production of 10,000 kilograms of 92-93 per cent H_2SO_4 in 24 hours:

DAILY PRODUCTION, 22,000 LBS., 92-93 PER CENT H_2SO_4, 98-99½ H_2SO_4

	Cascade.	Tower.	Kessler.	Improved.	Improved Kessler.
Coke consumed, lbs.	3,300	2,420 to 2,640	2,200 to 2,420	1,760 to 2,200	1,980 to 2,090

* Coal equivalent to 20 hp.

The Chemical Industries of America*

By Prof. Charles E. Monroe.

(*Concluded from page* 196.)

Having confessed myself, and having found my profession guilty, as charged, I now assert that a chief duty of our profession is to determine methods by which the income may be increased or the costs of living in the land decreased, or preferably both, and I urge as a first measure the advocacy of the policy of preventing any material from leaving the country until it has passed through all processes of manufactures of which it is capable. The meaning of this is evident on inspecspection of the exports of domestic merchandise prepared by the United States Bureau of Statistics, where we find that in 1908 over $885,000,000 worth, or 48.19 per cent of the total exports, consisted of cotton, breadstuffs, meat and dairy products, and coal, much of which had not undergone any degree of manufacture whatever. All this food should have been elaborated in this country into brain and brawn, and the coal made to yield its energy, and then should have been expended here in manufacture. We should further have put into manufactured form the raw materials of other lands.

Inspecting, on the other hand, the table of imports of merchandise prepared by the United States Bureau of Statistics we find that in 1908 but a little over $210,000,000 worth, or 17.87 per cent, of our imports consisted specifically of unmanufactured materials, such as silk, hides and skins, india rubber and gutta percha, wool, cotton, copper, lead and iron ores, and bristles, which would properly go into manufactures here.

We sit back glorying in our country. Its wide extent. Its rich resources. Its teeming millions of independent and self-respecting people. And yet after our fleet has circumnavigated the globe, we continue to sacrifice the fertility of our soils to the support of older civilizations and remain content, while ranging ourselves with those nations that live solely on their primary resources, since the "balance of trade" is in our favor. But we, as chemists, know that this condition cannot last. We know that the average fertility of our soil has been growing steadily less and that only by following sound scientific practice can the fertility of the impoverished soil be restored.

The utilization of the soil as a chemical factory is but one of the problems with which the chemist has to deal. That which appeals most nearly to us as chemical engineers is the item that appears as second in magnitude in the Table of Imports of Merchandise and which has held this second place for years, namely, "Chemicals, drugs and dyes," for this category embraces those substances commonly knowns as chemicals, or the products of the "black art." In 1908 we imported $73,237,033 worth of this class of materials, or 6.13 per cent of our total im-

*Address delivered, by invitation, on December 9, 1909, at the annual meeting of the American Institute of Chemical Engineers in Philadelphia.

ports, while we exported but $20,873,155 worth, or 1.14 per cent of our total exports. There was, therefore, a balance of $52,363,878 against us in this item, in which the chemical engineers of this country are most nearly concerned.

It is true that among these imports are upward of $15,000,000 worth of crude drugs and dyewoods, and quantities of other crude material, but there are many million dollars' worth of substances included here that should have been manufactured in this country. Attention need only to be called to the acids imported to a value of over $1,300,000 to emphasize this fact, for while we are seeking an outlet for our sawdust, we find in this list nearly 9,000,000 lb. of oxalic acid. Or attention might be called to the more than $7,000,000 worth of coal-tar products and preparations, not medicinal. Had this been accomplished there is little doubt that our exports of such substances would also have been large. And what is true of the industries commonly called chemical would equally apply to those larger chemical industries not included in the common category.

Another policy we should follow is the promotion of chemical manufactures throughout a larger portion of our great territory. For this purpose I have prepared Table VI, showing by States the locations of each of the 1786 establishments reported for chemicals and allied products at the census of 1905.

And I find that seven States or Territories, viz., Arkansas, Idaho, Montana, New Mexico, North Dakota, South Dakota and Utah, did not at that time possess a single establishment devoted to any of the large number of industries embraced in chemicals and allied products. Oklahoma, New Hampshire and Wyoming each possessed but one, and the District of Columbia, Nebraska, Nevada, Oregon, Texas and Vermont each less than five.

In order to bring this matter of the distribution of the industries manufacturing chemicals and allied products more clearly to your attention I have, through the courtesy of the director

TABLE VI—NUMBER OF ACTIVE ESTABLISHMENTS FOR CHEMICALS AND ALLIED PRODUCTS, BY STATES, 1905

	1905		1905
Alabama	27	Mississippi	7
Alaska	1	Missouri	47
Arizona	4	Nebraska	4
California	63	Nevada	3
Colorado	6	New Hampshire	1
Connecticut	40	New Jersey	144

*Corn oil cake not included

of the Bureau of the Census, had prepared a map* of the United States showing the location of the establishments, both principal and subsidiary, manufacturing sulphuric acid, those making explosives, and those engaged in wood distillation, each being a typical industry, and the sulphuric acid industry being generally accepted as of fundamental importance.

From this chart it appears that 13 States and Territories, being the seven already named (Arkansas, Idaho, Montana, New Mexico, North Dakota, South Dakota, Utah) with Iowa, Nebraska, New Hampshire, Nevada, Oregon, and Wyoming, containing 7,648,000 out of the 76,303,387 inhabitants of the continental United States in 1905, or over 10 per cent of the whole, did not possess a single establishment devoted to any one of these industries.
